Foreword

It is an honour to introduce to readers the fourth edition of Professor Alwyn Lishman's landmark book *Organic Psychiatry: The Psychological Consequences of Cerebral Disorder*, newly titled *Lishman's Organic Psychiatry: A Textbook of Neuropsychiatry*. Since its first publication in 1978, I have regularly referred to it in my clinical work and research on the psychiatric aspects of neurological disorders.

It was one of the first modern texts to compile knowledge of psychiatric aspects of neurological disorders, including cognition, mood, delusions, hallucinations, obsessions and phobia. Before its publication, patients who had neurological disorders were often deprived of expert psychiatric care, and clinical research workers could not take advantage of these experiments of nature to aid their search for brain-mind connections. *Organic Psychiatry* provided a basis for neuropsychiatric training, patient care and research.

Until early in the 20th century, neurology and psychiatry were, in a number of countries, considered to be a single discipline, but then neurologists such as Charcot and Freud postulated psychological and social roots for anxiety and abnormal behaviours, thus differentiating neurology from psychiatry. Soon, psychiatrists were receiving minimal neurological training and neurologists were receiving minimal psychiatric training. This separation had many consequences, not the least of which was the need for psychiatrists to be reintroduced to the psychiatric aspects of neurological disorders. Professor Lishman's historic text, in its several iterations, has filled this need and fostered the development of the subspecialty of neuropsychiatry.

Several psychiatrists who worked in the years prior to the publication of the first edition directly or indirectly influenced Lishman's work. Adolph Meyer, a psychiatrist and a neuroanatomist, invented a method for documenting the psychological and social context of mental states, now known as the 'case taking notes', which remains a framework for observations necessary for the formulation of individual cases and for research conjectures. At about the same time, Karl Jaspers published the monumental *General Psychopathology*. Jaspers was trained by Franz Nissl who was interested in cortical-subcortical connections and the correlation

of psychological states with blood vessels, glia and cortical structures. Jaspers' book defined the methods of psychiatry and also compiled the elements of the mental state to be explained or understood in relation to neurological and social conditions.

Organic Psychiatry also reflects the thought of Jaspers' colleague in Heidelberg, Wilhelm (Willi) Mayer-Gross. Mayer-Gross came to London in 1934 to work with Mapother at the Bethlem and Maudsley hospitals. In 1939 he moved to Birmingham to teach and conduct research in psychiatry. Lishman was to become a medical student there a decade later. Mayer-Gross's major influence on Lishman most likely came through his textbook, *Clinical Psychiatry*, which he wrote with Eliot Slater and Martin Roth. As a neurology resident I was delighted to find a psychiatric text that presented the material in a straightforward descriptive manner, similar to a textbook of internal medicine. *Clinical Psychiatry* included chapters on Alzheimer's disease and other neurological disorders that cause psychiatric symptoms. It published Meyer's case taking notes and a brief, scored cognitive examination that influenced my formulation of the Mini Mental State examination. Lishman generally followed Mayer-Gross's approach, expanding the sections on neurological disorder and more importantly providing evidence for and against assertions that a particular disease caused specific symptoms.

Finally, Lishman was encouraged to undertake the writing of the book by Aubrey Lewis, the first Chairman of the Institute of Psychiatry in London who created what Jaspers called 'the genius of place' that produced Lishman and many other important 20th-century psychiatrists. Denis Hill, who succeeded Lewis as Chairman, continued this encouragement and wrote the foreword to the first edition of the book.

Each and every chapter of the fourth edition of *Organic Psychiatry* has been comprehensively revised and updated by a small group of experts, lead by Tony David, Lishman's successor at the Maudsley Hospital/Institute of Psychiatry, who have maintained the tradition set by Alwyn Lishman and invigorated it. The new textbook has expanded sections

on neuropsychology and neuroimaging, both essential disciplines for neuropsychiatric practice and research. Neuropsychology developed from the localisationist ideas of Broca and Wernicke who discovered that discrete lesions of the brain were followed by disorders of language. This view has been replaced by the idea that dysfunction of cortical–subcortical networks has psychological effects. The modern field was initially based on the study of war injuries, and tried to localise psychological functions to discrete brain areas. Neuroimaging has in some ways supplanted or replaced the autopsy as a means for clinical pathological correlation. It has demonstrated the widespread cortical and subcortical networks involved in cognitive impairment and depression. Knowledge of the strengths and weaknesses of imaging technologies is critical for the work of neuropsychiatrists who should be able to evaluate scan results in relation to other clinical features. Interpretation must be cautious

because, as the authors note, a lesion seen may or may not be causally related to the clinical features.

Also included is a separate chapter on sleep disorders, a common group of conditions at the interface between neurology and psychiatry, and the elevation of Alzheimer's disease to the chapter title covering this and related dementias. This reflects both its importance as a global health issue and the huge advances in the understanding of its genetic basis and underlying pathophysiology.

The authors' accurate and critical descriptions of the cognitive and non-cognitive features of neurological diseases bring some clarity to these complex interpretations, which reflect the brain–mind relationships. The new edition, like the earlier editions, will be an indispensable guide for the work of psychiatrists, neurologists and neuropsychologists and all students and practitioners working in neuropsychiatry, a growing clinical field.

Marshal Folstein MD, June 2009
Professor of Psychiatry, Johns Hopkins
Medical Institutions; Professor of Psychiatry,
Tufts School of Medicine, USA

Preface to the First Edition

The impetus for writing a book on organic psychiatry has come largely from clinical practice and teaching. Both reveal the lack of focused knowledge concerning the overlapping territories between psychiatry and neurology – a gap manifested in the paucity of textbook literature on the subject. Clearly, as with any borderland zone, there has been a risk of relative neglect as each separate discipline has proceeded on its specialised way, leaving, perhaps inevitably, an uneasy interface between.

Neurology deals directly with the apparatus of mind by investigating malfunction of the brain. Yet paradoxically it has often paid scant attention to mental disorder itself. Psychiatry on its part deals essentially with mental disorder, yet has had little in relative terms to do with the hardware upon which mind depends. The rich complexity of human behaviour, and the multitude of factors which can shape and distort it, have clearly demanded a multifaceted growth of clinical psychiatry; the subject had profited from psychodynamic, psychosocial and pharmacological approaches to mental disorder, but with the expert neurologist waiting in the wings the factor of brain malfunction has sometimes tended to be eclipsed. Sir Denis Hill, in his Foreword to the book, has touched on the dilemma and set it in much wider historical perspective.

It has therefore seemed worthwhile to attempt a comprehensive review of the cognitive, behavioural and emotional consequences of cerebral disorder, and the problems in this area which are encountered in clinical practice. The task proved greater than at first envisaged. In the first place neurology and psychiatry with their attendant disciplines have both proceeded apace, sometimes drawing closer together and sometimes further apart in their different approaches to disease. The literature on their common ground has correspondingly flourished, but in a scattered manner. Secondly it soon became obvious that a text devoted to psychiatric disorders associated with structural brain disease would be unduly restrictive, and that certain metabolic, toxic and other systemic disorders must also be considered if brain malfunction was to be the central theme.

Others could have argued for the inclusion of a good deal more than is here presented. Very little will be found on mental subnormality or child psychiatry since such fields are beyond the author's competence. And the temptation to speculate in detail on possible 'cerebral' contributions to the major functional psychoses has been resisted. Boundaries have in general been drawn short of hypothetical situations, and the work is mainly confined to disorders of cerebral function which are indubitable and well established.

Within the selected field coverage of different topics will no doubt be found inequitable. An avowed preoccupation with focal cerebral disorder, and the light which disease has thrown on regional brain function, will be apparent to the reader. But other considerations have also been at work. Some very rare disease processes are given considerable attention when their psychiatric components can on occasion be important or when important lessons have been learned from them. Similarly the selection of case reports will sometimes illustrate rare conditions or phenomena, if case presentation seems much better than lengthy description for communicating the essence of the matter. In the sections on treatment, physical approaches will often be described in more detail than psychotherapeutic or social interventions, without any necessary assumption that these have less important parts to play in overall management of the patient. Thus in many respects the emphases in the book must be construed, not as reflecting the absolute importance of a topic, but rather the particular slant indicated in a work devoted to organic aspects of psychiatry. Finally if scant attention seems to have been paid to purely psychological reactions to physical disorder this in no sense implies that such aspects are less intriguing or practically important. Matters of space and time, and the patience of the reader, have dictated that lines must be drawn, however arbitrarily and painfully.

Acknowledgements for the help of others are traditionally given, but the list would be long indeed if I were to pay tribute to all the teachers, colleagues and students who have fostered my interest and guided my thinking on the subjects

dealt with herein. I will list instead those who have been directly concerned with the book and have often spent generous hours in detailed discussion and the reading of drafts. The late Sir Aubrey Lewis took a keen and encouraging interest in the earlier stages of the work. Sir Denis Hill has given both detailed criticism and constant helpful support. I am greatly indebted to him for generously providing a Foreword to the book. Special thanks must go to Dr Richard Pratt for reading large parts of the manuscript and allowing me to draw on his exceptional knowledge of the literature. Those who have criticized individual sections and chapters include Professor Frank Benson, Professor Robert Cawley, Dr Elaine Drewe, Dr Griffith Edwards, Professor George Fenton, Dr John Gunn, Dr Derek Hockaday, Dr Raymond Levy, Professor David Marsden, Dr David Parkes, Dr Felix Post and Dr Sabina Strich. Others who have helped in innumerable ways include Dr Christopher Colbourn, Mrs Isobel

Colbourn, Dr John Cutting, Dr May Monro, Dr Maria Ron and Dr Brian Toone. Miss Helen Marshall put at my disposal her unrivalled expertise in guiding me to the rich store of information in the Institute of Psychiatry library. To all of these kind friends and colleagues I am very deeply grateful.

Finally I must record my gratitude to the two people who have been most intimately concerned of all. Mrs Dorothy Wiltshire has not only collaborated on an arduous task, but has positively welcomed the burden and done much to sustain my enthusiasm. Her expert secretarial skills and untiring patience have, in effect, made the venture possible. My wife, Marjorie, deserves the warmest thanks of all – meticulous help with the manuscripts and with problems of the English language have been but a tiny part; over several years she has paved the way, deflected obstacles and taken over numerous burdens in an ever-helpful manner which is most affectionately acknowledged.

Alwyn Lishman, June 1977

Preface to the Fourth Edition

When Alwyn Lishman suggested that I might edit the fourth edition of his famous tome my reaction was one of huge delight mixed with equal trepidation. It took five co-editors with the help of some young and energetic colleagues to finally complete the task, a fact that only goes to emphasise his monumental achievement in bringing about the previous three editions of *Organic Psychiatry*. It is clearly no longer tenable for a single person to maintain the level of detailed analysis and standard of exposition across the entire breadth of neuropsychiatry that Lishman set, given the explosion in neuroscientific and clinical insights over the last two decades.

The team of co-editors in many ways selected themselves, being firmly rooted in complementary aspects of neuropsychiatry, currently working as clinicians and academics at the Maudsley Hospital/Institute of Psychiatry and having various degrees of affiliation with Alwyn Lishman. I would like to take this opportunity to thank them for their undying enthusiasm, painstaking hard work and good humour.

This fourth edition has a new title that honours Lishman's original accomplishment but makes it clear that this is not a cosmetic makeover but a new textbook. The awesome task that was required of us was to somehow preserve the single authoritative authorial voice of Alwyn Lishman while at the same time bringing new perspectives and clinical research to bear on the topics of neuropsychiatry. The clinical descriptions are, of course, timeless and these have been left largely intact, but new classificatory systems, new understandings in biology and, to some extent, new treatment approaches have displaced much of the previous edition. Thanks to our sub-editors and publisher the format has been rendered more easy on the eye, with highlighted text and boxes of information. There are many more tables and illustrations. However, there has been no attempt to 'dumb down' the content. Readers seeking a quick and easy fix to ignorance in neuropsychiatry should look elsewhere.

The basic chapter structure remains although we begin with the principles of neuropsychiatry, which incorporates the previous small chapter on differential diagnosis. The

next chapter is, as pointed out by Marshal Folstein, a new departure and brings in more neuropsychology which is of course a bedrock science for neuropsychiatry. The clinical assessment chapter includes illustrations, particularly of magnetic resonance brain images, as this is such a dominant diagnostic tool. The first chapter in the 'disorders' section is Head Injury, by Simon Fleminger, and brings in a raft of new material both in terms of pathophysiology and prognosis. The Cerebral Tumours chapter by Drs Fleminger and Mellado Calvo has also been extensively revised and it is pleasing to see more on treatment and effects of treatment in this chapter. John Mellers has carried out many fundamental revisions and additions to the Epilepsy chapter reflecting new approaches to classification, diagnosis and treatment in that field. In Intracranial Infections, Simon Fleminger, ably abetted by Mike Dilley, takes on infections of historic significance and very modern conditions, such as HIV-AIDS which Lishman introduced in the third edition, knowledge of which has now matured through the introduction of effective chemo- and immunotherapy. This is followed by the last of Simon Fleminger's contributions, Cerebrovascular Disorders, which contains information on new vascular syndromes of importance in neuropsychiatry. Simon Lovestone, a Professor of Old Age Psychiatry, has taken on Alzheimer's disease and other dementias. This chapter bears little resemblance to its equivalent in the previous edition, reflecting the massive strides in the understanding of Alzheimer's and related dementias from a molecular genetic point of view. The next two chapters, on endocrine/metabolic disorders and toxic disorders were both led by Mike Kopelman with the help of Neil Harrison, Lawrence Reed and Mayur Bodani. These chapters show considerable reworking from the previous edition but with toxic disorders, including effects of alcohol, continuing to exert its full weight. Indeed, in some respects the term 'organic psychiatry' more readily encompasses such issues, whereas neuropsychiatry can be interpreted in a very narrow sense as only applying to diseases of the brain. Clearly our preferred usage of neuropsychiatry includes the whole range of conditions that can affect brain and mind, directly and indirectly. In the movement disorders

chapter John Mellers and Max Henderson bring recent discoveries in molecular genetics to the understanding of Parkinson's disease, dystonias and less common disorders of the basal ganglia. The next chapter is on sleep and related disorders and is ably managed by Mike Kopelman and Meryl Dahlitz. Sleep disorders were previously embedded within a 'ragbag' final chapter but such are the advances in the field that we felt that this cluster of very common as well as some esoteric disorders deserves a chapter in its own right. However, there remains the necessity for a final chapter bringing together other miscellaneous disorders and Simon Lovestone manfully took this on. It includes as before, psychiatric aspects of multiple sclerosis and neuromuscular conditions plus the paraneoplastic neuropsychiatric syndromes that in many ways constitute 'breaking news'; even

now there are novel disorders to be discovered and described.

It has been a privilege to steer this effort to completion. It has been a wondrous, if sometimes tortuous, journey. Many people, too numerous to name, have helped along the way: clinicians, managers, neurophysiologists, neuropsychologists, etc. Special mention should go to the late Ginny Ng, consultant neuroradiologist who provided some of the MR images and helped educate all of us in their interpretation and, more recently, Naomi Sibtain, who has carried on this tradition. The publishers in their various incarnations have remained steadfastly behind the project. Finally, the greatest thanks must go to Alwyn Lishman himself for inspiring all of us to carry on his work and for providing a benign watchful presence as we do so.

Anthony S. David, January 2009

I am deeply grateful to my younger colleagues who have produced this new edition of 'Organic Psychiatry', and particularly to Professor Tony David who bravely undertook to coordinate their efforts. They have, at a stroke, liberated me from a somewhat daunting task, and at the same time brought the book forward into the new millennium.

When I look back on the preparation of previous editions I realise the extent of the debt I then owed to day-to-day clinical practice, coupled with the stimulation afforded by colleagues, students and research associates, not to mention the availability on site of a first-class library. In short, the unique atmosphere of the Institute of Psychiatry kept me, almost insensibly, abreast of progress. Now, well into my retirement, I have been forced to recognise that without this special environment it would be foolhardy to attempt to update the text once more myself.

The next important step was to free the new editors in turn, and leave them to proceed unfettered by any intrusions on my part. I could not have taken so bold a decision without

close acquaintance with all of the editors and having the utmost confidence in them. They are clearly present-day leaders in the neuropsychiatric field and with special interests that bring added strengths to their capabilities for the task.

It has been a privilege to witness the extraordinary growth of interest and progress in this sub-specialty of psychiatry since the era when the first edition of the book was published in 1978. In part, this has derived from the astonishing advances in the neurosciences that have made brain structure and function increasingly relevant to mental, as well as neurological, disorder, also in part from the rapprochement between neurologists, psychiatrists and neuropsychologists as they pursue overlapping areas of research and clinical endeavour. The consequent burgeoning of knowledge and its attendant literature have gradually made it unrealistic for a single author to attempt to encompass the subject matter satisfactorily. My appreciation and my indebtedness towards the architects of this fourth edition are therefore great indeed.

Alwyn Lishman, January 2009

While every effort has been made to ensure the accuracy of the drug dosage and side-effects described in the book, the authors and publisher make no representation, expressed or implied, that they are correct. The reader is advised to refer to published information from the pharmaceutical companies and other reference works to check accuracy.

The distinction between symptoms and signs that is customary in general medicine is often difficult to make where psychological phenomena are concerned. To avoid repetition, 'symptoms' will often be used alone when both the patient's complaints and the psychological abnormalities detected by the examiner are being considered together. For similar reasons 'he' or 'his' will often be used when 'he/she' or 'his/her' would be more appropriate and correct.

PART 1

Principles

Basic Concepts in Neuropsychiatry

Anthony S. David

Institute of Psychiatry, King's College, London

What is neuropsychiatry?

In most psychiatric illnesses the clinical picture is profoundly coloured and sometimes decisively shaped by factors specific to the individual and his environment. Hence the notorious difficulty in identifying separate disease processes in psychiatry. This is compounded still further, where most mental disorders are concerned, by the lack of collateral evidence by means of tissue pathology. Alwyn Lishman used the term 'organic psychiatry' to describe those disorders 'in which there is a high probability that appropriate examination and investigation will uncover some cerebral or systemic pathology responsible for, or contributing to, the mental condition'. He contrasted this with the term 'neuropsychiatry', which he took to be a more specific discipline at the interface between neurology and psychiatry, concerned with disorders that can be demonstrated to owe their origins 'to brain malfunction of a clearly identifiable nature' and thus not including endocrine, toxic and metabolic disorders. While these disorders operate via disturbances in brain function, they are, according to Lishman, the concern of general medicine rather than neurology. Despite the clarity and merits of this distinction, 'neuropsychiatry' has become the more widely used term and is generally not used in its more restrictive sense. It is used here synonymously with organic psychiatry but broader still to include those conditions that might appear at first sight to be caused by pathology of the nervous system with manifestations in the neurological domain, but which turn out not to be so; in fact psychological and social factors predominate in the clinical formulation – in other words, the so-called conversion disorders. Inclusion of such disorders may be justified on pragmatic grounds since they contribute to a sizeable proportion of the workload of the neuropsychiatrist and related health professional. Further, the differential diagnosis of conversion is, by definition, neurological; likewise, conversion dis-

orders contribute to the differential diagnoses of most neuropsychiatric conditions.

Before leaving the issue of definitions, it is worth reiterating here two other aspects dealt with by Alwyn Lishman in his preface to the second and third editions of his textbook. First, we wholly subscribe to Lishman's injunction that neuropsychiatry 'must capitalise on all that psychiatry has to offer' including psychodynamic, social and cultural aspects, and that 'neuropsychiatric practice requires a widening not a narrowing of psychiatric skills and interests'. Second, neuropsychiatry does not claim to be the only branch of psychiatry where the brain and other biological systems are relevant, far from it. The term 'biological psychiatry' is rightly reserved for the approach (rather than the clinical discipline) concerned with 'pathophysiologicals of a biological nature' which can be brought to bear on increasingly numerous if not all forms of psychiatric disorder to varying extents.

The psychological disturbances which result from brain pathology often share common ground that cuts across differences in background, personality and social situation. They are related to pathological processes within the brain, or acting on the brain, which can often be identified by the techniques of medical investigation. In these respects neuropsychiatry draws closer to the rest of medicine, and should at least in theory be amenable to a similar approach in leading towards useful clinicopathological correlations.

In large measure this is so. However, psychological symptoms are hard to identify objectively and can rarely be measured accurately. Difficulties of assessment increase abruptly as we ascend from basic motor and sensory processes to mental phenomena, and especially when we move from simple cognitive impairments to changes in emotion, personality and other complex aspects of behaviour. Moreover, when symptoms characteristic of the neuroses or major psychoses emerge in the brain-damaged person, it is necessary to consider the possibility that he may have been specially

predisposed to their development. Ultimately, indeed, we are often forced back again to the problems of the main body of psychiatry, since the more complex effects of cerebral disorder can be properly assessed only when the whole individual is viewed in the context of his personal history and environment. The situation is therefore a good deal more complex than in most other branches of medicine, and the opportunities for relating abnormalities of behaviour to precise aspects of cerebral pathology are limited in several important respects.

Fortunately for the diagnostic process, neuropsychiatric disorders tend to have certain features in common that usually allow them to be distinguished from non-organic mental illnesses. Different varieties of pathological change are often associated with similar forms of impairment. Bonhoeffer (1909), who coined the term 'exogenous psychoses', deserves the credit for recognising this and discarding the Kraepelinian view that each noxious agent affecting the brain evokes a specific psychiatric picture. Impairment of consciousness, for example, may result from a number of toxic processes acting on the brain or from raised intracranial pressure; dementia may result from anoxia, from trauma or from primary degenerative disease. It is therefore possible to extract important symptoms and syndromes that indicate the possibility of cerebral disorder whatever the basic pathology and despite the colouring lent by pathoplastic features. Such symptoms form the cornerstone of diagnosis in neuropsychiatry and it is essential to recognise their earliest and most minor manifestations. Many disease processes affecting the brain will come to attention with psychological symptoms alone and well before the appearance of definite neurological signs, and it is often by the correct appreciation of these common forms of reaction that a mistaken diagnosis of non-organic (or so-called 'functional') psychiatric disorder will be avoided.

Other forms of presentation may indeed occur with change of personality, affective disturbance, neurotic symptoms or even pictures indicative of schizophrenia. The clinician must remain aware that occasionally a mental illness presenting in this way may be related to the early stages of cerebral disease. Such cases are not infrequent and their detection by judicious application of ever more sensitive and non-invasive investigations such as magnetic resonance imaging increasingly likely; however, as the condition progresses, organic mental symptoms will usually appear.

Basic concepts and terminology

This chapter describes various frameworks for grouping together the cardinal psychological symptoms and signs of cerebral disorder. The principal accent will be on the shared forms of reaction common to most individuals and to different pathological processes, though features particular to individuals are also briefly described where appropriate. The feature that distinguishes neuropsychiatric

disorders from the rest of psychiatry is cognitive impairment.

A main division is the temporal one, i.e. 'acute' and 'chronic' reactions. These terms are clinically useful for broad classification and for shorthand description of groups of clinical phenomena. A topographical distinction, namely 'focal' versus 'generalised' or 'diffuse', can be superimposed on this temporal division, so that both acute and chronic conditions can be focal or diffuse in nature.

Acute versus chronic cerebral disorder

Acute organic reaction and *chronic organic reaction* are the terms best used for the first major division of organic psychiatric illnesses, each functioning as no more than a pointer to a class of problems, and serving only as starting points for further enquiries into aetiology. These terms carry implications for abruptness and onset and to some extent for the constellation of symptoms most in evidence. Each may show features not seen in the other, and requiring specific approaches for their identification. The terms also carry implications for likely duration, but not directly for ultimate prognosis. It is more usual for acute than for chronic organic reactions to recover, but the prognosis in each case will depend on the precise aetiology at work. A separate category of 'subacute organic reactions' is sometimes demarcated, and merely implies less sudden onset than the acute disorders, somewhat longer continuation, and an admixture of clinical symptoms characteristic of acute and chronic reactions. It must be accepted, however, that both acute and chronic reactions will vary in the degree of their acuteness or chronicity, and that in some cases the former will, with time, prove to merge into the latter.

The temporal dimension or time course is one of the most critical indicators in the evaluation of chronic neuropsychiatric conditions. The clinical course of the disorder reveals many clues as to its nature. These may be variously described as progressive, stepwise, relapsing and remitting, etc. A progressive course implies degeneration or the gradual expansion of a space-occupying lesion. A stepwise course classically describes the intermittent but accumulating deficit as a consequence of repeated vascular events. A relapsing and remitting course suggests an inflammatory processes, such as multiple sclerosis, especially where each relapse adds a residuum of impairment or disability. Acute disturbances followed by complete recovery suggest disorders of function such as physiological disruptions to cerebral or neural activity without the enduring stamp of tissue pathology, as occurs with electrical disturbances or transient metabolic upsets or indeed a 'non-organic' aetiology.

Generalised versus focal cerebral disorder

A great number of organic psychiatric disorders are due to widespread disturbance of brain function. This may be the result of diffuse disease processes within the brain, as in certain degenerative diseases, or of systemic disturbances, for example those leading to anoxia which impair brain function indirectly. Moreover, well-localised brain lesions may declare themselves only when secondary diffuse effects supervene, as with raised intracranial pressure in association with cerebral tumour. The majority of acute and chronic organic reactions therefore reflect widespread disorder of cerebral activity and contain symptoms of defective function in many spheres.

It has become customary to talk of 'generalised cerebral disorder' and to distinguish this from the effects of strictly focal pathology. However, it must be appreciated that both generalised and focal disturbances of brain function represent theoretical extremes that are rarely if ever encountered in practice. It is most unlikely that intrinsic brain disease is ever uniformly distributed throughout the brain, and some degree of focal emphasis can usually be discerned with careful observation. Extrinsic factors that impair brain function are likewise selective in their effects, sparing some neural or neurochemical systems while disrupting others. Impairment of consciousness, for example, represents interference with brainstem alerting functions while cardiovascular and respiratory functions are little affected. Similarly, disruption of cortical and subcortical functions very rarely occurs to an equivalent extent.

Strictly focal disorder, on the other hand, is also very rare except when purposely produced by surgical procedures. In naturally occurring disease we merely see a focal emphasis of pathology, which in greater or lesser degree is complicated by the additional effects of damage elsewhere.

Nevertheless it is of great importance in practical clinical terms to preserve the distinction between clinical pictures that result from widely disseminated or from relatively circumscribed brain dysfunction. The distinction is essential in the formulation of likely causes and thence in deciding the lines which investigation must follow. Each, in practice, contains different symptoms of fundamental importance.

The plan in this chapter will be first to describe in broad terms the characteristic clinical pictures seen in 'generalised' acute and chronic reactions, and then to summarise the salient features seen with focal damage or focal emphasis of pathology in specific brain regions. The focal significance of certain symptoms and symptom complexes is dealt with in more detail in Chapter 2.

Commonly used terms

The following are some commonly used terms of general clinical description.

Confusion refers to symptoms and signs which indicate that the patient is unable to think with his customary clarity and coherence. Cognitive impairment is often used nowadays as a portmanteau term in preference to confusion. It is seen in both organic and non-organic mental disturbances, and the term is useful merely as a shorthand clinical description of an important aspect of such mental states. In acute organic reactions, confusion is due largely to impairment of consciousness. In chronic organic reactions, it betrays the disruption of thought processes due to structural brain damage. In a whole range of psychiatric disorders, confusion of thinking may be much in evidence without any identifiable brain pathology whatever; similarly when powerful emotions from any cause interfere with the efficient ordering of cognitive processes. The term 'toxic confusional state' is widely used but can properly be applied only when toxic influences on the brain have been established.

Clouding of consciousness denotes the mildest stage of impairment of consciousness which is detectable clinically, on the continuum from full alertness and awareness to coma. As such it is manifest as slight impairment of thinking, attending, perceiving and remembering, in other words as mild global impairment of cognitive processes in association with reduced awareness of the environment. The patient will frequently, though not always, appear to be drowsy but this is not to be confused with the normal transition to sleep.

Twilight states. Among Bonhoeffer's 'forms of exogenous reaction' due to pathogenic factors acting on the brain, twilight states and delirium were separately demarcated. The essential features appear to include abrupt onset and ending, variable duration from hours to weeks, and the interruption of quiet periods of behaviour by unexpected and sometimes violent acts or outbursts of rage or fear. Other descriptions include dream-like 'oneiroid' states, vivid hallucinations and delusional ideas that dictate powerful affective disturbance. Clearly, therefore, the term is used to cover a variety of syndromes and can now have little useful meaning. It is, moreover, widely employed to describe hysterical manifestations in addition to acute organic reactions (particularly some types of complex partial seizure).

Coma represents the extreme of a graded continuum of impairment of consciousness, at the opposite pole of the spectrum from full alertness and awareness of the environment. The patient is incapable of sensing or responding adequately to external stimuli or inner needs, shows little or no spontaneous movement apart from respiration, and no evidence whatever of mental activity.

Coma is itself a graded phenomenon. At its deepest there is no reaction to stimuli of any intensity, and corneal, pupillary, pharyngeal, tendon and plantar reflexes are absent. Respiration is slow and sometimes periodic (Cheyne-Stokes respiration) and cardiovascular regulating processes may

show signs of failure. Lighter degrees of coma (semicoma) allow partial response to stimulation, though this is incomplete, mostly non-purposive and usually consists of ineffectual movements or rubbing and scratching of the stimulated area. Bladder distension may call forth groaning or ill-coordinated motor stirring but the patient is still incontinent. Tendon reflexes may or may not be obtainable, and the plantars may be either flexor or extensor. The Glasgow Coma Scale, which has proved its usefulness for the grading of depth of coma, is described in Chapter 4, Measuring head injury severity.

Coma needs to be distinguished from deep sleep and from stupor. In deep sleep and in coma the pictures may be closely similar on superficial observation, but the sleeper can be roused again to normal consciousness by the efforts of the examiner. He may wake spontaneously to unaccustomed stimuli, or in response to inner sensations such as hunger or bladder distension. In sleep there is sporadic continuing mental activity in the form of dreams which leave traces in memory. Coma is more difficult to demarcate from stupor, which is described below. The distinguishing features usually accepted are that in coma the eyes remain shut even in response to strong arousal stimuli, do not resist passive opening, and do not appear to be watchful or follow moving objects; movements in response to stimulation are never purposeful, and there is no subsequent recall of events or inner fantasies from the time in question (see also persistent vegetative state, Chapter 4).

Stupor is an exceedingly difficult term to define, principally because it has been used widely in neurological and psychiatric practice to refer to conditions with markedly different causation. Sometimes it is used loosely and wrongly to refer to an intermediate stage on the continuum of impairment of consciousness that leads ultimately to coma; sometimes to refer to a syndrome characteristic of lesions in the neighbourhood of the diencephalon and upper brainstem and called akinetic mutism; and sometimes to clinical states superficially similar to this but due to hysterical, depressive or schizophrenic illness. Stupor is thus a term without definite nosological status, but valuable when properly used in referring, in essence, to a clinical syndrome of akinesis and mutism but with evidence of relative preservation of conscious awareness. There is a profound lack of responsiveness, and evidence of impairment, or at least putative or apparent impairment, of consciousness. Speech and spontaneous movement are absent or reduced to a minimum, and the patient is inaccessible to the great majority of external stimuli. Unlike coma and semicoma, however, the patient may at first sight appear to be conscious, since the eyes may be open and seem to be watchful. The patient may direct his gaze towards the examiner and the eyes may follow moving visual stimuli in a manner which appears to be purposeful rather than random. When the eyes are shut

they may resist passive opening. Relative preservation of consciousness is also betrayed by the response to stimulation: strong painful stimuli may induce blinking or purposeful coordinated efforts to dislodge the noxious agent. Moreover, in some cases there is subsequent recall of events or delusional fantasies occurring in the stuporose state.

Typically, spontaneous movements are absent but there may be tremors, coarse twitching or, in light stupor, restless stereotyped motor activity. The latter may seem to occur in response to hallucinatory experiences, or to display special meaning in stupors due to psychotic illness. Here also the resting posture may be awkward or bizarre, or it may be meaningful in the context of the patient's delusions. Reflexes are usually entirely normal. Complete mutism is the rule, but again there may sometimes be partially coherent muttering, or arousal may be possible to the extent of brief stereotyped exclamations. In light stupor there may be no sphincter disturbance, and even feeding may be possible with coaxing. Simple responses to commands may then be obtained, though these are slow, inaccurate and often ill-coordinated. The least severe examples may merge indefinitely with severe psychomotor retardation in psychotic depression, or with severe blocking of thought and volition in catatonic schizophrenia. The causes of stupor and their differential diagnoses are considered later in this chapter.

Organic personality change. Brain damage often results in changes of temperament, or changed patterns of reaction to events and to other people. As a result, behavioural tendencies that have previously been enduring characteristics of the individual are found to be altered. Areas typically affected include the control of emotions and impulses and aspects of motivation and social judgement (Lipowski 1980). Such 'change of personality' is usually prominent in dementia, and is then seen along with cognitive defects. But sometimes brain damage may operate more directly by disruption of regional cerebral systems upon which the synthesis of the personality depends. This situation is compatible with excellent preservation of intellect to formal testing, yet the personality change is nonetheless organic in origin. Thus when disturbance of cognitive processes cannot be identified, the term 'organic personality change' is preferable to 'dementia'. Most examples occur with strictly focal brain damage, the best known being with lesions of the frontal lobes of the brain. A clear discontinuity between the current and premorbid personality is essential if this term is to retain its meaning.

Chronic amnesic syndrome. Disorder of memory, especially for recent events, is an integral part of dementia, but can also exist without global impairment of intellect. Such memory disturbance may emerge as the sole defect, as after bilateral hippocampal lesions, or more commonly may stand out as the obtrusive defect while other cognitive processes are but little affected. Such a syndrome may follow an acute organic

reaction which clears to reveal a relatively isolated defect of memory, as when Wernicke's encephalopathy leads to Korsakoff's syndrome.

The term 'chronic amnesic syndrome' usefully describes the essential features of disorder in all such cases, and emphasises the distinction from dementia. It may be defined as an organic impairment of memory out of all proportion to other cognitive changes. A focal rather than a diffuse brain pathology can be confidently predicted as described. Unfortunately, the terms 'chronic amnesic syndrome' and 'Korsakoff's amnesic syndrome' are sometimes used interchangeably, the territory of the latter being allowed to expand considerably. Strictly speaking, the term 'Korsakoff's syndrome' should be restricted to those patients whose amnesia depends on lesions in the hypothalamus and diencephalon and is consequent upon thiamine deficiency.

Organic hallucinosis refers to a syndrome of recurrent or persistent hallucinations, occurring in a setting of full preservation of consciousness and awareness of the environment yet attributable to organic factors. The patient is not disoriented and proves capable of thinking with normal clarity throughout. The hallucinations occur mostly in the auditory or visual modalities but any sensory modality can be affected. Insight into the unreal nature of the phenomena may vary markedly in degree, but any delusions that occur are secondary to the hallucinatory experiences. Such a syndrome may be occasioned by circumscribed brain lesions, strategically placed to irritate cortical or subcortical areas, but is more commonly seen as a result of toxic processes. The hallucinations occurring during the early phase of alcohol withdrawal or after ingestion of hallucinogenic drugs are typical examples.

The prototypical acute and chronic organic reactions are delirium and dementia respectively. These have been operationally defined in the two current major classificatory systems, the Diagnostic and Statistical Manual of Mental Disorders (DSM)-IV and the International Classification of Diseases (ICD)-10 (Boxes 1.1 and 1.2).

Delirium. There are many meanings and definitions of this term, sometimes embracing all varieties of acute organic reaction, sometimes referring to the degree of overt disturbance, and sometimes confining its use to clinical pictures with certain specific features. Special characteristics have included wakefulness with ability to respond verbally, increased psychomotor activity, pronounced disturbance of affect, defective reality testing, or the appearance of productive symptoms in the form of illusions and hallucinations. Delirium tremens is often taken as a prototype for delirium, and contrasted with the 'simple confusion' of subdued cognitive impairment in other illnesses, although this is categorised separately in DSM and ICD. In the UK it was formerly

Box 1.1 DSM-IV and ICD-10 classifications of delirium

DSM-IV criteria

- A** Disturbance of consciousness (i.e. reduced clarity of the environment) with reduced ability to focus sustain or shift attention.
- B** A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance.
- C** The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
- D** There is evidence from the history, physical examination or laboratory findings that the disturbance is caused by the direct physiological consequences of a general medical condition/substance intoxication/withdrawal/multiple aetiologies. [Each subcategory has its own additional criteria including 'Delirium not otherwise specified'.]

ICD-10 criteria

- (a)** Impairment of consciousness and attention, with reduced ability to direct, focus, sustain, and shift attention.
- (b)** Global disturbance of cognition: perceptual distortions, illusions and hallucinations, mostly in the visual modality; impairment of abstract thinking and comprehension; impairment of immediate recall and recent memory; disorientation for time and sometimes place and person as well.
- (c)** Psychomotor disturbance which may consist of hypoactivity or hyperactivity or unpredictable shifts between the two.
- (d)** Disturbance of the sleep-wake cycle: insomnia, daytime drowsiness, sleep reversal; nocturnal worsening of symptoms; or disturbing dreams and nightmares which may continue as hallucinations on awakening.
- (e)** Emotional disturbances: depression, anxiety, fear, irritability, euphoria, apathy or perplexity.

traditional to reserve the term for patients whose acute cerebral disorder resulted in some degree of disturbed or disruptive behaviour, i.e. to emphasise the restless hyperactivity and emotional disturbance which is so commonly part of the picture. It is clear, however, that not all patients who meet current criteria for delirium present like this, some showing predominant listlessness, inertia and dulling of the senses. In a daily evaluation of 125 patients who met DSM-III criteria for delirium in a general hospital, Liptzin and Levkoff (1992) classified 15% as hyperactive, 19% as hypoactive, 52% as mixed and 14% as neither.

It is important to appreciate that consciousness is not merely quantitatively reduced in delirium, but also qualitatively changed. Typically the patient becomes preoccupied with his own inner world which is distorted by illusions, hallucinations and delusions, and sometimes by powerful

Box 1.2 DSM-IV and ICD-10 classifications of dementia

For an ICD-10 research diagnosis of dementia (World Health Organization 1993) there must be evidence of the following.

- 1** A decline in memory affecting both verbal and non-verbal material, sufficient at least to interfere with everyday activities.
- 2** A decline in other cognitive abilities, characterised by deterioration in judgement and thinking and in the general processing of information. Deterioration from a previously higher level of performance should be established. For a confident diagnosis both 1 and 2 must have been present for at least 6 months.
- 3** Preserved awareness of the environment during a period sufficiently long to allow the unequivocal demonstration of the symptoms in 1 and 2; when there are superimposed episodes of delirium, the diagnosis of dementia should be deferred.
- 4** Decline in emotional control or motivation, or a change in social behaviour manifest as at least one of emotional lability, irritability, apathy or coarsening of social behaviour.

DSM-IV specifies individual criteria for dementia of the Alzheimer-type, vascular dementia, etc., the common elements being as follows.

- A** The development of multiple cognitive deficits manifested by both:
 - 1** memory impairment;
 - 2** one or more of aphasia, apraxia, agnosia or disturbance of executive function (planning, organising, sequencing, abstracting).
- B** Such cognitive deficits cause significant impairment in social or occupational functioning, and represent a significant decline from a previous level of functioning.
- C** The course is characterised by gradual onset and continuing cognitive decline.
- D** The deficits do not occur exclusively during the course of a delirium.

Further inclusion and exclusion criteria then apply to the several varieties of dementia specified in DSM-IV.

affective changes derived therefrom or more directly from dysfunction of specific brain systems. Even though awareness of external events is impaired, arousal may be high, enabling these productive symptoms to occur. The fluctuations in severity are commonly accompanied by fluctuations in content, manifesting as a continuously changing clinical picture. Many different disturbances of cerebral function can lead to delirium, with little that can be regarded as specific in the clinical pictures that result. Toxic and metabolic disturbances are perhaps prone to be associated with listlessness and apathy, and infective processes and alcohol withdrawal syndromes with hyperactivity, fearfulness and prominent hallucinations.

DSM-IV divides the syndrome into delirium due to a general medical condition, substance-induced delirium, and delirium due to multiple aetiologies (American Psychiatric Association 1994). Fundamental to all is a disturbance of consciousness (i.e. reduced clarity of awareness of the environment) coupled with a reduced ability to focus, sustain or shift attention. Additional requirements are a change in cognition (such as memory deficit, disorientation or language disturbance) or the development of a perceptual disturbance (misinterpretations, illusions or hallucinations, mainly visual), with the proviso that these are not better accounted for by a pre-existing or evolving dementia. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.

The ICD-10 classification (World Health Organization 1992) similarly stresses concurrent disturbances of consciousness and attention, along with changes in cognition, perception, psychomotor behaviour, sleep-wake cycle and emotion. The disorder is usually rapid in onset, with diurnal fluctuations, most cases recovering within 4 weeks or less but sometimes continuing for up to 6 months.

'Dementia' is used in two contexts which must be clearly distinguished: first to label a group of specific disease entities, and secondly to refer to a clinical syndrome that can have many other causes. The specific diseases for which the term is used are considered in Chapter 9. They are characterised by progressive and widespread and inexorable brain degeneration. When denoting a syndrome, however, the term may validly be used more widely, and can be defined very simply as an acquired global impairment of intellect, memory and personality, but without impairment of consciousness. As such it is almost always of long duration, usually progressive and often irreversible, but these features are not included as part of the definition.

The syndrome therefore consists of a constellation of symptoms that suggest chronic and widespread brain dysfunction. Global impairment of cognition or intellect is the central and essential feature, manifest as difficulty with memory, attention, thinking and comprehension. Other mental functions are usually affected concurrently, and changes of mood, personality and social behaviour may sometimes be the outstanding or even presenting features. Nevertheless 'dementia' should not be used to describe such changes unless intellectual deterioration can be identified.

Historically the term has acquired implications for inevitable decline and irreversibility. This remains true for the disease entities of dementia, but not for all the settings in which the syndrome may appear. The dementia accompanying general paresis can be arrested, and that due to head injury or normal-pressure hydrocephalus may improve with time or treatment. We are now in a new era of effective treatment for Alzheimer's and related dementias, at least in the short and medium terms. Thus when matters of prognosis

are excluded from the definition, the term can be used whatever the cause of the syndrome and whatever future therapeutic discoveries may bring.

It is also important that the syndrome be defined in terms of global impairment of cognitive functions and not in terms of diffuse cerebral damage. Focal brain damage can sometimes lead to global impairment of intellect, memory and personality in addition to regional deficits. Frontal lobe tumours are notorious in this regard, and can produce a picture of dementia indistinguishable at first sight from other causes. In such cases it remains logical to use the term to describe the clinical picture which presents for attention, even though diffuse affection of brain tissue is not the immediate cause. Indeed some forms of dementia are best regarded as the end-result of multiple focal pathologies that coalesce and combine to impair functions globally, as in the vascular dementias. It is essential, therefore, to avoid defining the syndrome in terms of a pathology which has yet to be displayed.

The term is thus reserved for the description of a group of clinical symptoms, while all considerations of prognosis and aetiology are excluded from the definition. This has a certain practical importance, in that once the syndrome has been identified it must always dictate a search for ultimate causes. These may be focal or diffuse, within or without the brain, and may have possibilities for treatment.

Clinical picture in acute organic reactions (acute brain syndrome, acute confusional state, 'delirium')

The acute organic reactions are called forth by a great number of different pathological processes affecting the brain, including trauma, cerebral anoxia, epilepsy, metabolic derangements such as uraemia, or the toxic effects of drugs or alcohol. A list of causes is presented in Table 1.1. The onset is always fairly abrupt, though when slight in degree the disorder may not declare itself in an obvious fashion from the outset. The majority of acute organic reactions are reversible when the underlying pathology can be remedied, but some may progress directly to a chronic organic syndrome, as when an acute post-traumatic psychosis clears to reveal dementia or when Wernicke's encephalopathy results in an enduring amnesic syndrome.

The clinical pictures which result are essentially due to disruption of normal brain function by virtue of biochemical, electrical or mechanical disturbances. The symptomatology follows a surprisingly constant pattern despite these various causes. To some extent there are specific features depending on rate of development, the intensity and perhaps the nature of the noxious agent, but this variability is small in relative terms. The personality and background of the patient will also colour the picture, especially in minor affections and particularly where matters such as intensity of emotional

disturbance or content of delusional thinking are concerned. The main emphasis in what follows, however, will be on shared and common forms of reaction. There is a growing tendency to treat delirium as a problem in its own right with an epidemiology, collection of risk factors, prognosis and treatment strategies (see Burns *et al.* 2004 for review). This reverses years of neglect as a topic for clinical research. The settings in which delirium is most commonly seen, outside those in which acute infections of the central nervous system (CNS) are endemic, are services for the elderly, those undergoing palliative care and in the postoperative situation, especially following cardiothoracic procedures. Simple but comprehensive medical and nursing procedures to minimise and reduce the impact of delirium have now been the subject of clinical trials (Britton & Russell 2004). It is obvious that treatment of delirium should target the underlying cause, but managing a very disturbed patient in the mean time often requires judicious use of parenteral antipsychotic drugs or short-acting benzodiazepines.

Impairment of consciousness

Impairment of consciousness is the primary change in acute organic reactions, and in some degree is universal. It therefore holds a fundamentally important place in the detection of acute disturbances of brain function and in the assessment of their severity. Other features, such as disordered psychomotor activity, perception and emotion, may be more striking but are less constantly found and are also more variable in their manifestations.

Impairment of consciousness lies on a continuum that ranges from barely perceptible dulling of awareness to profound coma. Characteristically the impairment fluctuates when mild in degree, often worsening at night with fatigue and with decreased environmental stimulation. The fluctuations and the appearance of lucid intervals are observations of great clinical importance in the differential diagnosis of organic from non-organic psychiatric disorders, and also in distinguishing acute from chronic organic reactions. Daytime visits may find the patient at his best, and it is thus essential to pay attention to reports of changed behaviour as nightfall approaches.

Disorders of attention

In most conditions impairment of consciousness is accompanied by diminished arousal and alertness which become clinically apparent at some stage of the disorder. However, in others, such as delirium tremens, the patient may be hyperaroused and hyperalert. Arousal and alertness, in this context, refer to the readiness with which the patient responds to environmental stimuli, 'arousal' being best used to describe the physiological state of the organism and 'alertness' to describe the observational data from which this state is inferred.

However, preserved alertness is not the sole yardstick by which preservation of normal consciousness is assessed. To be useful alertness must be coupled with an ability to select discriminatingly between

Table 1.1 Causes of acute organic reactions.*Degenerative*

Dementias complicated by infection, anoxia, etc.

Episode in Lewy body dementia

Space-occupying lesions

Cerebral tumour, subdural haematoma, cerebral abscess

Trauma

'Acute post-traumatic psychosis'

Infection/inflammation

Encephalitis, meningitis, HIV infection, subacute meningovascular syphilis, exanthemata, streptococcal infection, septicaemia, pneumonia, influenza, typhoid, typhus, cerebral malaria, trypanosomiasis, rheumatic chorea

Vascular

Acute cerebral thrombosis or embolism, episode in multi-infarct dementia, transient cerebral ischaemic attack, subarachnoid haemorrhage, hypertensive encephalopathy, systemic lupus erythematosus

Epileptic

Complex partial seizures, petit mal status, postictal states

Metabolic

Uraemia, liver disorder, electrolyte disturbances, alkalosis, acidosis, hypercapnia, remote effects of carcinoma, porphyria

Endocrine

Hyperthyroid crises, myxoedema, Addisonian crises, hypopituitarism, hypoparathyroidism and hyperparathyroidism, diabetic precoma, hypoglycaemia

Toxic

Alcohol: Wernicke's encephalopathy, delirium tremens

Drugs: benzodiazepines and other sedatives (including withdrawal), salicylate intoxication, cannabis, LSD, MDMA ('ecstasy'), prescribed medications (antiparkinsonian drugs, scopolamine, antidepressants, steroids, antiretrovirals, anticonvulsants, etc.)

Others: lead, arsenic, organic mercury compounds, carbon disulphide

Anoxic

Bronchopneumonia, congestive cardiac failure, cardiac dysrhythmias, silent coronary infarction, silent gastrointestinal bleeding, carbon monoxide poisoning, post anaesthesia

*Vitamin lack*Thiamine (Wernicke's encephalopathy), nicotinic acid (pellagra, acute nicotinic acid deficiency encephalopathy), B₁₂ and folic acid deficiency

LSD, lysergic acid diethylamide; MDMA, 3,4-methylenedioxymethamphetamine.

those stimuli which are important and meaningful and those which are not. Moreover, the relevant stimuli must gain access to conscious awareness where they can be related to past experience and present needs. For these purposes alertness must be accompanied by a capacity to attend. When consciousness is impaired, certain qualities of attention will invariably be found to be defective, qualities referred to as *phasic*, *modulated*, *selective* or *directed* attention.

These involve the capacity not merely to allow a stimulus to elicit a response, but to mobilise, focus, sustain and shift attention in a fluid and changing manner according to the needs of the moment. Whether the patient is hypoalert or hyperalert, it will often soon become apparent that such mechanisms are at fault. Failure to be selective can result in indiscriminate, often excessive, responses to stimuli with the result

that the patient is *distractible*; failure to mobilise and sustain attention is seen in *impaired concentration*; inability to shift attention can lead to *perseveration*. The examiner's difficulty in engaging with the patient may owe much to all these factors. A more pervasive change may also occur, whereby internal percepts, thoughts and images come to hold attention more readily than percepts from the environment, allowing them to become elaborated in an unrestrained manner. This would appear to be important in the genesis of the vivid affects, fantasies and hallucinations of 'delirium', as described earlier in this chapter.

A true appreciation of the patient's level of consciousness must therefore include assessment not only of alertness and responsivity, but also of capacity to attend in a discriminating manner to what is going on around.

A minor degree of impairment of consciousness may present merely with complaints of vague malaise and feelings of uncertainty. It may escape detection at the time and be revealed only in retrospect by the amnesic gap left for the period in question. Other sensitive indicators are minor difficulties in judging the passage of time, in focusing attention as described above, or in thinking coherently. The latter again may initially be more apparent subjectively than to external observation. Sometimes there may be neglect of appearance and of needs, or an episode of incontinence may be an early sign. The sleep–wakefulness cycle is almost universally disturbed in some degree, with various combinations of insomnia, vivid dreams and dream-like mentation (Lipowski 1980, 1990). The diurnal rhythm of activity is sometimes clearly disordered, with a tendency to somnolence by day and excitability at night.

With more severe degrees of impairment, the patient is observed to be slow in responding, loses the thread in conversation, and attention to outside events is hard to arouse and sustain. Responses to requests may betray inadequate understanding or lack of volition to carry them out. Later still the patient is clearly drowsy, sleeps excessively and, if rousable, shows only a torpid and muddled awareness.

Psychomotor behaviour

Motor behaviour usually diminishes progressively as impairment of consciousness increases. When left alone the patient shows little spontaneous activity and habitual acts such as eating are carried out in an automatic manner. The capacity for purposive action is diminished. When pressed to engage in activities the patient is slow, hesitant and often perseverative. He responds to external stimuli apathetically if at all, though highly charged subjective events such as hallucinatory experiences may still call forth abrupt and even excessive reactions. Speech is slow and sparse, answers stereotyped or incoherent, and difficult questions are usually ignored. There is often slurring, perseveration, or dysphasic difficulties. In severe cases there may be no more than incoherent muttering.

While the above is the rule with most acute affections of the brain, some show the reverse with restless hyperactivity and noisy disturbing behaviour. Delirium tremens and the deliria which accompany certain systemic infections are the well-known examples. Not surprisingly these florid cases figure disproportionately highly in most published accounts of acute organic reactions. Psychomotor activity is greatly increased, with an excessive tendency to startle reactions. Typically the overactivity consists of repetitive, purposeless behaviour, such as ceaseless groping or picking movements. Behaviour may be dictated by hallucinations and delusions, the patient turning for example to engage in imaginary conversation, or ransacking the bedclothes for objects thought to be hidden there. More rarely he may perform complex

stereotyped movements, re-enacting the driving of a car or miming his usual work (occupational delirium). Sometimes there is dangerously belligerent behaviour. When purposive, the activities are usually misdirected, inappropriate or bizarre, and voluntary movements are often jerky and uneven. The overactivity is often accompanied by excitement with noisy shouting, laughing or crying. There may be pressure of speech with incoherent flight of ideas. Most of the behaviour is obviously dictated by the patient's own internal world, and alertness to external stimuli is seen to be impaired. Not uncommonly the clinical picture shows rapid changes from phases of overactivity to periods of apathy and spontaneity.

Thinking and reasoning

Thought processes show characteristic changes when consciousness is impaired. In the early stages there is subjective slowing, with difficulty in focusing thoughts or formulating complex ideas. Mental fatigue may be obvious in the course of examination. Later, reasoning becomes less clear and coherent, logic is impaired and thinking is more concrete and literal. Even when speeded by high arousal, the thought content is seen to be banal and impoverished. Trains of thought become chaotic, showing in speech as fragmentation and incoherence.

An important change is in the relative importance of the internal and external worlds, and in the decreasing ability to preserve the distinction between the two. Thus perceptions and thoughts become inextricably interwoven (defective 'reality testing'). Comprehension of events is impaired, with inability to embrace the elements of experience and relate them meaningfully to one another (impaired 'grasp'). The patient may be unaware of the most obvious features of his situation, whether he is standing or lying, whether indoors or in the street. At the same time increased significance is attached to subjective experiences, ideas or false perceptions, which come to dominate the content of consciousness. Bizarre thoughts and fantasies intrude into awareness, and false significance is attached to external cues. Illusions and hallucinations readily arise, and vivid dream material may be carried over into waking life.

Ideas of reference and delusion formation may become prominent, depending to some extent on qualities in the pre-morbid personality. Delusions of persecution are especially common, and may well up suddenly with conviction. They usually betray their organic origin in being poorly elaborated, vague, transient and inconsistent. When consciousness is relatively clear, however, the delusions may be more coherently organised, with a picture more closely resembling schizophrenia. In rare cases delusions may persist when the patient has recovered from the acute illness, with an obstinate belief in the reality of the hallucinatory experiences that occurred.

Insight into cognitive difficulties is typically lost early, but may vary with fluctuations in the level of consciousness. Sometimes even in moderately severe affections the patient may be briefly roused to self-awareness and to a better appreciation of reality.

Memory

With impairment of consciousness there is disturbance of registration (encoding and learning), retention and recall. Registration of current experience is hampered by defects in attention, perception and comprehension. Accordingly, the immediate memory span for digits or similar material (working memory) is found to be reduced. Defective retention leads to difficulty with new learning and this is a sensitive clinical indicator in mild stages of disorder. Recent (episodic) memories prove to be faulty while long-term memories are reasonably intact, though with moderate impairment of consciousness both are found to suffer.

An early change is defective appreciation of the flow of time, and the jumbling of time sequences for recent events. This quickly leads to disorientation in time, which is sometimes regarded as the hallmark of acute organic reactions. However, disorientation may be transient in the early stages, and a normally orientated patient may prove later to be amnesic for all that passed during the interview in which he was examined.

Disorientation for place, and later still for person, follow with worsening of perceptual and cognitive disorganisation. Patients may maintain two incompatible attitudes towards their orientation without seeming aware of the inconsistency. This can emerge strikingly where orientation for place is concerned, the patient saying quite correctly, for example, that he is in hospital in one town yet interpreting his surroundings and behaving in every other way as though he were at home in another part of the country, a condition known as reduplicative paramnesia. Such correct and incorrect orientations may exist side by side in a vacillating and unrelated manner, or be reconciled by shallow rationalisations. The patient may insist that the two places are the same, or contiguous with each other, or confabulate a recent journey between the two. Reduplicative paramnesias may take a number of forms and are sometimes associated with misrecognition or reduplication of persons. They can be seen with chronic organic reactions as well, perhaps particularly in association with right hemisphere pathology (Ellis & Lewis 2001; see also Illusions of transformation, displacement or reduplication, later in this chapter). False memories and confabulation may occasionally be in evidence, and misidentifications, including pseudorecognition, are facilitated by the perceptual abnormalities described below.

On recovery there is typically a dense amnesic gap for the period of the acute illness, though where fluctuation has been marked islands of memory may remain. Sometimes sensory impressions, and especially vivid hallucinations,

stand out clearly and are remembered in great detail when all else is forgotten, attesting again to the importance of subjective experience over external reality in severe stages of the disorder.

Perception

Quite commonly it is the more florid perceptual abnormalities that draw attention to the presence of an acute organic reaction in a patient suffering from some physical disease. However, these are not essential features in every case, and the diagnosis should be made by seeking out the subtle deficits in thinking, memory and attention which betray impairment of consciousness.

Early on the patient may be aware that perception requires unusual effort, particularly where vision is concerned. Sometimes, in contrast, perceptions appear subjectively to be hyperacute. Disturbances of vision include micropsia, macropsia or distortions of shape and position. Disordered auditory perception may hinder clear communication. There may be distortions of weight and size, or bizarre disorders of the body image in which body parts feel shrunken, enlarged, misplaced or even disconnected. The whole body may feel as though it is tilted or floating. Disordered perception of internal bodily sensations leads sometimes to bizarre complaints. Genuine physical symptoms such as vertigo, headache and paraesthesiae are likewise often reported in distorted fashion.

Depersonalisation and derealisation are common, though usually incompletely expressed. Dissolution of the perceptual boundaries between the self and the environment may give rise to terrifying feelings of imminent dissolution or loss of bodily and personal integrity.

Perceptual abnormalities readily lead to misinterpretations and illusions which are typically fleeting and changeable. The visual modality is affected most often. Difficulty with visual recognition combines with faulty thinking and memory to produce false recognitions and faulty orientation in place. The unfamiliar tends to be mistaken for the familiar, or may be interpreted as hostile or persecutory. Thus the patient may misidentify a nurse as a relative, or the doctor as an old friend or enemy. The hospital ward may be mistaken for home or prison. Chance noises may similarly be misinterpreted, contributing to delusion formation. The whole is often reinforced by disordered affects of fear and suspicion.

Hallucinations are also commonest in the visual modality, though tactile and auditory hallucinations occur as well. They probably derive partly from failure to distinguish inner images from outer percepts, and partly from vivid dreams carried over into the waking state as consciousness waxes and wanes. Simple visual hallucinations consist of flashes of light, geometrical patterns or colours. More complex phenomena, sometimes kaleidoscopic in nature, may occur, with fully formed hallucinations of scenes, people and animals. A bizarre fantastic quality is not uncommon. The hallucinated

material may be grossly distorted, as with Lilliputian hallucinations where objects and people appear to be minute in size. The reality of the phenomena is fully accepted by the patient, who may react with fear and alarm but sometimes with interest or even amusement.

Hallucinations appear to be particularly characteristic of the acute organic reactions occasioned by certain pathological processes. Delirium tremens remains the classic example, with extremely florid hallucinations as described in Chapter 11. Along with hallucinogenic drugs, prescribed drugs with potent anticholinergic properties are also notorious for the wealth of formed and unformed hallucinations they may provoke. Animals are said to feature particularly frequently in the hallucinations of delirium tremens, and visual hallucinations of 'nets' were said to characterise the organic reactions seen in bromide intoxication when this was common. In the setting of delirium, sensory impairments appear to predispose to hallucinations in the corresponding modality and hence are common in the elderly.

Emotion

In early stages, mild depression, anxiety and irritability may be expected, though typically the affect is shallow. With deeper impairment, and further impoverishment of mental processes, apathy usually becomes the striking feature, and the whole course of the illness may pass with indifference and emotional withdrawal. More lively affects are seen in conjunction with increased psychomotor activity when affective disturbance may become intense. Anxiety and fear are especially common, increasing sometimes to terror and panic. A state of wondering perplexity forms a common background to other affective states. Depression is frequent, elation or anger less so. Paranoid attitudes may show in marked hostility and suspicion. The affective reactions are often fleeting and changeable with changing delusional ideas. Sudden displays of primitive and highly charged emotion are often called forth by hallucinatory experiences.

In part the emotional state is likely to be determined by the stress of the physical illness, and in part by a vague awareness of cognitive impairments. The individual's personality structure may contribute in considerable measure, some patients being predisposed to react by apathetic withdrawal and others by projection of fantasised dangers onto the environment. The extent of such influences has not been determined, nor the degree to which the picture is shaped by different pathogenic agents. There are strong clinical impressions that delirium tremens tends to be accompanied by intense fear, hepatic encephalopathy by euphoria or depression, and uraemia by apathy, but reliable and systematic comparisons have not been made. It is clear, moreover, that several factors are often operative together in leading to delirium in the individual patient, particularly in the elderly (Francis *et al.* 1990).

Other features

In the milder stages in particular, the definitive organic features may be less in evidence than those which depend on individual traits and characteristics. Psychological reactions to early cognitive impairment, or to the stress of the underlying physical disease, may dominate the picture and emerge in the form of neurotic symptoms. Similarly, vulnerable aspects of personality may be exaggerated, with the appearance of depressive, hypochondriacal or phobic features. Histrionic and importunate behaviour may sometimes be much in evidence. Hysterical conversion symptoms, usually transient but sometimes persistent, may lead to mistakes in diagnosis. Paranoid developments occur frequently, and can become the overriding feature at an early stage in susceptible individuals. A distinct schizophrenic colouring to the total clinical picture is likewise not uncommon. With progression of cognitive disorganisation the true situation usually becomes apparent, but mild self-limiting acute organic reactions can be misdiagnosed for some time as non-organic psychiatric illness.

Clinical picture in chronic organic reactions (chronic brain syndrome, chronic confusional state, 'dementia')

Chronic organic reactions, like acute organic reactions, result from many different pathological processes, yet the clinical picture shows a large measure of similarity from one condition to another. A focal emphasis of pathology may produce special patterns of impairment, but the purpose in what follows is to describe the general clinical picture and to emphasise the shared and common forms of reaction that occur.

While the majority of chronic organic reactions are due to diffuse and widespread affections of the brain, some owe their origins to focal pathology, so careful examination for signs of localising value must always be undertaken. The principal causes are listed in Table 1.2. Most of the illnesses concerned are slowly progressive with increasing disablement, but static pictures may be seen as with arrested general paresis, or gradual improvement may occur as after head injury. In a small but extremely important group, therapeutic intervention can decisively reverse the process, for example with myxoedema or normal-pressure hydrocephalus, or when a frontal meningioma is discovered to be the cause.

Mode of presentation

Some chronic organic reactions follow acute episodes such as trauma or anoxia, and are then revealed in full when the patient recovers consciousness, or else emerge by a process of transition from an acute organic reaction. The great majority, however, develop insidiously from the start.

Table 1.2 Causes of chronic organic reactions.*Degenerative*

Alzheimer's disease, multi-infarct dementia, Lewy body dementia, frontal lobe dementia, Pick's, Huntington's and Creutzfeldt–Jakob diseases, normal-pressure hydrocephalus, multiple sclerosis, Parkinson's, Schilder's and Wilson's diseases, progressive supranuclear palsy, progressive multifocal leucoencephalopathy, progressive myoclonic epilepsy, metachromatic leucodystrophy, neuroacanthocytosis, Kufs' disease, mitochondrial myopathy, etc.

Space-occupying lesions

Cerebral tumour, subdural haematoma

Trauma

Post-traumatic dementia

Infection/inflammation

HIV-associated dementia, general paresis, chronic meningovascular syphilis, subacute and chronic encephalitis, multiple sclerosis

Vascular

Cerebral vascular disease, *état lacunaire*, cerebral autosomal-dominant arteriopathy with subcortical leucoencephalopathy (CADASIL)

Epileptic

'Epileptic dementia'

Metabolic

Uraemia, liver disorder, remote effects of carcinoma

Endocrine

Myxoedema, Addison's disease, hypopituitarism, hypoparathyroidism and hyperparathyroidism, hypoglycaemia

Toxic

Korsakoff's syndrome, 'alcoholic dementia', chronic intoxication with sedative drugs, manganese, carbon disulphide

Anoxic

Anaemia, congestive cardiac failure, chronic pulmonary disease, post anaesthesia, post carbon monoxide poisoning, post cardiac arrest

Vitamin lack

Lack of thiamine, nicotinic acid, B₁₂, folic acid

The commonest mode of onset is with evidence of impairment of memory or more general cognitive impairment with disorganisation of intellect. Failures of memory are usually noted earlier by relatives and workmates than by the patient himself. They show in missed appointments, apparent unawareness of recent happenings, a tendency to mix up times or to lose things. More general cognitive failure emerges in slipshod work and loss of overall efficiency. The patient may be noticed to think and speak less coherently than usual, to muddle money or to fail to grasp essentials.

Change in personality as the first manifestation is much less common, but when it occurs the patient is especially likely to come before the psychiatrist. Here intellectual deficits are mild or absent in the early stages, or pass unnoticed because of curtailment of activities and the use of props and evasions. Deterioration of manners may be the earliest sign,

or diminished awareness of the needs and feelings of others. Some social blunder may disclose the problem, such as stealing or disinhibited behaviour out of character for the individual. Sometimes the earliest change is merely the exaggeration of long-standing personality traits such as suspiciousness or egocentricity. Neurotic traits may be elaborated with the production of depressive, obsessional, hysterical or hypochondriacal symptoms. More rarely the illness presents with the picture of a psychotic illness of depressive, paranoid or schizophrenic type in especially predisposed individuals. It is then only by careful examination that the onset of cognitive impairment is revealed.

Whatever the form of presentation, the illness may declare itself abruptly even though its evolution has been insidious. Some episode of acute mental disturbance may bring the disease to attention. Or relatives may have adjusted to the

slow decline until some dramatic instance forces their attention to the true situation. Not infrequently a tenuous adjustment is concealed until new demands must be met, for example on the death of a partner or a move to a new environment. Admission to hospital may be the step which reveals the disorder, and only careful retrospective enquiry then establishes that the onset has been gradual. Intercurrent illness may bring the situation to light by pushing the patient below the threshold at which the brain was previously coping, especially infection, anoxia or postoperative metabolic derangements.

General behaviour

Although cognitive impairment is the hallmark of chronic organic reactions, this may be manifest only indirectly by way of behavioural change. Typical early signs are loss of interest and initiative, inability to perform to the usual standard, or minor episodes of muddle and confusion. Episodes of bizarrely inappropriate behaviour may occur, as when a woman unloads her shopping in the oven or prepares a meal at an inappropriate time. As described above, some cases present with changes in the field of social behaviour well before impairment of cognitive processes is overt.

As the disorder progresses the same division is seen, some aspects of behaviour reflecting the intellectual disorganisation, and some the change in emotional control and social awareness. Intellectual impairment shows as incapacity for decisive action, loss of application and inability to persist in a consistent course of conduct. Despite full alertness and the preservation of normal levels of consciousness the patient fatigues readily on mental effort. He responds appropriately to stimuli within his limited range of comprehension and is capable of directed attention as the need arises, but powers of concentration are impaired. Various behavioural changes may come into play that reflect the attempts of the personality to cope with such defects. There is often restlessness, with purposeless overactivity or, alternatively, rigid adherence to routines and stereotyped behaviour. In this manner the patient may be enabled to cope for a while. When taxed beyond his ability, however, he may become evasive and sullen, or react abruptly with an explosion of primitive affect such as anger, anxiety or tears ('catastrophic reaction' after Kurt Goldstein). In the later stages hygiene and personal appearance are neglected and ritualistic hoarding may develop. Food is eaten sloppily, habits deteriorate and there is indifference to urinary or faecal incontinence. In contrast, however, some patients preserve superficial social competence until surprisingly late in the course of the disease.

Eventually, behaviour becomes futile and aimless, often with stereotypies and mannerisms. Impoverishment of thought is reflected in lack of purposive activity, and physical deterioration follows with increasing weakness and emaciation.

Thinking

Thinking is impaired both qualitatively and quantitatively. It becomes slowed with reduced powers of concentration and ready mental fatigue. The content of thought is impoverished, with fewer associations, inability to produce new ideas, and a tendency to dwell on set topics and memories from the past. Themes are banal and perseveration usually marked. The ability to reason logically and to manipulate concepts is impaired, likewise the ability to keep in mind various aspects of a situation simultaneously. Specific skills such as calculation are usually impaired from an early stage.

Intellectual flexibility is lost, leading to difficulty in shifting from one frame of reference to another. The lack of effective counter-ideas leads the patient to become tied to the immediate situations that arise, so that he is distracted by accidental impressions and events and becomes 'stimulus bound' to them. Such difficulties are compounded by inability to extract the essentials of a situation or experience. Abstract ideas present especial difficulty and concepts tend to be given their most literal interpretation (termed 'concretisation').

Judgement is impaired early. The patient's insight is poor and there may be little awareness of illness at all. The more the complexity of the domain of functioning, the greater the discrepancy between the individual's appraisal of his abilities and that of his carer. False ideas readily gain ground and paranoid ideation is particularly common. Ideas of reference may reflect an exaggeration of premorbid tendencies. Delusions are typically persecutory in nature and may owe much to limbic dysfunction (Cummings 1992). The complexity of their content tends to be inversely proportional to the severity of cognitive impairment, patients with severe dementia usually harbouring only simple and loosely structured false beliefs. Occasionally, however, they become entrenched and unshakeable. As Roth and Myers (1969) point out, they may be delusions in the technical sense, in that the beliefs are held in the face of evidence of their falsehood, but this is largely because the evidence fails to be understood not because it is rejected. Delusional themes are often crude and bizarre, typically of being robbed, poisoned, threatened or deprived. The exception is delusional misidentification, which appears to be particularly associated with organic brain changes. In the later stages thinking appears to be restricted to circumscribed reiterative themes, and becomes grossly fragmented, incoherent and disorganised.

Speech

The disturbances in thinking are mirrored in speech. The most characteristic disturbance is poverty of speech with excessive employment of clichés and set phrases. The pool of vocabulary is greatly reduced, and speech initiative is poor.

Sentences are often simple, incomplete and poorly constructed, with perseveration, stereotyped utterances and echolalia.

Paraphasic errors, and nominal dysphasia, are not uncommon. Barker and Lawson (1968) suggest that difficulty in word-finding is a general feature in dementia if care is taken to test with words of low frequency of usage. There may be little evidence of disability until the patient is pressed to name an object, whereupon he may show little awareness of his errors. This is in contrast to the situation in nominal dysphasia due to focal brain lesions. Sometimes he may improvise to produce new words, showing perseveration and 'clang' associations. Concretisation shows in the excessive use of words which refer to the self and the tendency for external stimuli to influence the words that are chosen.

Ultimately, speech becomes grossly disorganised and fragmented, and used exclusively in the service of bodily needs. The patient may become mute or capable only of a restricted range of semicoherent ejaculations.

Memory

Memory disturbance is frequently the earliest sign of a developing chronic organic reaction, and at first may be intermittent. Allison (1962) makes the important point that with diffuse as opposed to focal cerebral lesions the onset of memory disturbance can rarely be dated accurately because it has been of such gradual evolution. The onset may be marked by minor forgetfulness and 'absent-mindedness', or by more definite episodes in which new impressions fail to register and striking lapses of memory occur. Loss of topographical memory is often seen, with the patient losing his way when away from home. Disorientation in time is a frequent early sign; disorientation for place and person are found much later in development.

The memory defect is typically global, affecting all categories of material and remote as well as recent events, as described in Chapter 2. Failure at new learning is usually the most conspicuous sign, but rarely there is the sharp demarcation between remote and recent memory that characterises the purer amnesic syndromes. Recall is affected as well as registration and retention, as shown by increased success with prompting and better performance at recognition than at free recall. Memory for names is sometimes particularly affected. Temporal sequences are disorganised early, with faulty appreciation of the flow of time and mislocation of past events. Berlyne (1972) found that over one-third of an unselected group of demented patients showed unequivocal confabulation, sometimes representing a true memory displaced in time, but sometimes consisting of more sustained and elaborate productions.

Characteristically the patient's awareness of his memory difficulties is impaired, or there may even be an apparently

motivated desire to hide the deficits with facile excuses and shallow confabulations. In the early stages the patient may show surprising ingenuity in covering up his failures, and may compensate by means of a rigid daily routine and the use of a notebook. Ultimately, however, memory for current events may fail completely and the patient may be able to produce only a few jumbled recollections from the past.

Emotion

Emotional changes form an integral part of the clinical picture in chronic organic reactions and deterioration of emotion and intellect frequently pursue a parallel course.

Early emotional changes probably reflect the struggle to cope with incipient intellectual deficits, and are coloured by premorbid personality characteristics. Anxiety is common, likewise depression with agitation and hypochondriacal features. Serious suicidal attempts may occur at this stage. Irritability leads to querulous morose behaviour, and sometimes to outbursts of anger and hostility. Perplexity and suspicion are other common early developments, leading to paranoid beliefs and attitudes.

Further deterioration produces emotional changes of a distinctive organic type. Affective blunting and shallowness may progress to states of apathy or empty euphoria. Emotions may take on a child-like aspect, with petulant importunate behaviour and short-lived excessive responses to trivial annoyances. Thus the death of a spouse may leave the patient unmoved, yet interference with some simple routine may provoke outbursts of anger.

Emotional control may show a characteristic threshold effect in which there is little response to mild stimulation but thereafter an excessive and prolonged disturbance. Emotional lability may be extreme, with episodes of pathological laughing and crying for little or no cause. The 'catastrophic reaction' may be observed when the patient is taxed beyond his ability to cope, as described in Chapter 2 (Psychiatric disturbance and aphasia) and Chapter 3 (Mood).

The ultimate picture in progressive disease represents a combination of these various emotional changes, but characterised above all by increasing emptiness of affect, shallowness, dullness and lack of emotional response.

Other features

The impact of chronic diffuse brain disease is not entirely unaffected by features specific to the individual. As already mentioned, neurotic manifestations may be conspicuous in mild stages of disorder. Hysterical conversion symptoms and obsessional disorders may figure prominently, the former perhaps by virtue of increased suggestibility and the latter as a mode of coping with reduced resources. A predisposition towards affective or schizophrenic psychosis may lend a distinctive colouring to the clinical picture and lead to mistaken diagnosis in the early stages. Hallucinations can

occur in visual, auditory and tactile modalities, and are typically paranoid in content. With progressive disease all such manifestations are usually ultimately engulfed in the general pattern of intellectual and social decline.

The combination of acute and chronic organic reactions is of course much more common than would be predicted by their chance co-occurrence. Delirium superimposed on dementia is a common clinical problem and is recognised in international disease classificatory systems. Indeed, a dementing condition may be exposed for the first time by the superimposition of delirium following a relatively minor metabolic or toxic insult, due to the unnoticed loss of some theoretical cerebral 'reserve'. Other general psychiatric disorders when they occur in the setting of organic brain disease may be classified separately in the ICD and DSM schemes from their 'idiopathic', 'non-organic' counterparts.

Clinical picture in focal cerebral disorder

Strictly focal brain damage can be responsible for both acute and chronic organic reactions as well as rather characteristic 'neurobehavioural syndromes'. Symptoms and signs of localizing significance may then be much in evidence, and must be kept in mind in the clinical assessment of all patients who show organic psychiatric illnesses.

Epileptic phenomena, especially those of temporal lobe epilepsy, are clear examples of acute psychological disturbances due to focal brain dysfunction, also some of the disturbances seen after small acute cerebrovascular accidents. Wernicke's encephalopathy is another classic example, with its own distinctive chronic end-state in the chronic amnesic syndrome. For obvious reasons, however, focal brain disorder has been most comprehensively studied in slowly progressive or static lesions of long duration, which allow the focal components to be disentangled from any generalised deficits that coexist.

In Chapter 2, the complex problems of the focal significance of psychological symptoms are dealt with in detail. Here, those which emerge with fair consistency after lesions of different parts of the brain are described in summary form. Neurological defects are in general more reliable than psychological symptoms in pointing to the site of focal pathology, and these too will be included. In general focal signs and symptoms serve only to indicate the site of likely pathology, and are of relatively little value in themselves in suggesting the nature of the lesion.

Frontal lobes

Frontal lesions may confer distinctive changes of disposition and temperament subsumed under the term 'change of personality'. Most characteristic is disinhibition, with expansive over-familiarity, tactlessness, over-talkativeness, childish

excitement (*moria*) or prankish joking and punning (*Witzelsucht*). Social and ethical control may be diminished, with lack of concern for the future and for the consequence of actions. Sexual indiscretions and petty misdemeanours may occur, or gross errors of judgement with regard to financial and interpersonal matters. Sometimes there is marked indifference, even callous unconcern, for the feelings of others. Lack of insight into their social inappropriateness or the presence of any perturbation of health and functioning is characteristic. Elevation of mood is often seen, mainly as an empty and fatuous euphoria rather than as a true elation that communicates itself to the observer. In other cases the principal changes are lack of initiative, spontaneity and profound slowing of psychomotor activity, particularly with frontal lobe tumours. This may progress to a state of extreme spontaneity amounting virtually to stupor.

Concentration, attention and ability to carry out planned activity are impaired by these changes, but performance on tests of formal intelligence is often surprisingly well preserved once the patient's cooperation has been secured. Even with sharply circumscribed frontal lesions, however, the overall picture may at first sight strongly resemble a generalised dementing process. The hazards of misdiagnosis are increased by the 'silent' nature of frontal lobe lesions, which can allow them to grow large before declaring themselves with neurological signs.

When frontal lesions encroach upon the motor cortex or motor projections there will be contralateral spastic paresis, usually seen earliest in the face and more obvious on voluntary movement than emotional expression. Paresis may be extremely slight, and show only as slowness of repeated movements or falling away of the outstretched arm. A grasp reflex may be the only definite sign. Firmer evidence may be found in hyperactive tendon reflexes and a positive Babinski response. Characteristic decomposition of gait may be seen, with trunk ataxia or awkward postures.

Lesions affecting the orbital part of the frontal lobes may be associated with the 'forced utilisation' of objects presented to the patient, as described in Chapter 2 (Classical case reports). This appears to be an extension of the more commonly observed forced grasping. Posterior lesions of the dominant lobe may produce a primary motor dysphasia, a motor agraphia or an apraxia of the face and tongue. Ipsilateral optic atrophy or anosmia may result from orbital lesions of the lobe, the latter being commonly overlooked in clinical examination. Sphincteric incontinence may occur surprisingly early in view of the reasonable preservation of intellect, and is a valuable added indication.

Parietal lobes

Parietal lobe lesions are associated with a rather bewildering variety of complex cognitive disturbances, including defects of language and number sense, defective appreciation of

external space, and disorders of the body image. Where some are concerned it is uncertain how far the lesions of the parietal lobe are alone responsible, or how far adjacent lesions in the temporal and occipital lobes contribute to the total picture. These matters are dealt with in Chapter 2, but the following is presented as a brief clinical guide.

Lesions of either parietal lobe may result in visuospatial difficulties and topographical disorientation. Visuospatial difficulties are most readily exposed by asking the patient to copy simple drawings or construct patterns from coloured blocks or matchsticks, tests which reveal the presence of visuospatial agnosia or constructional dyspraxia. Defective performance is seen more commonly with lesions of the non-dominant than dominant lobe but may occur with either. Difficulty in locating objects in space, or in describing the relationships between different objects by vision alone, may also be observed. Topographical disorientation is revealed by difficulty in learning or remembering the way about, with the result that the patient mislocates his bed in the ward, fails to find the bathroom or loses himself even in familiar surroundings.

Dominant parietal lobe lesions are associated with various forms of dysphasia, primary motor dysphasia being most in evidence with anterior lesions and primary sensory dysphasia with posterior lesions. The latter may include alexia in association with agraphia. Motor apraxia similarly accompanies dominant parietal lobe lesions, and usually affects the limbs of both sides of the body. Various components of Gerstmann's syndrome may be seen, namely finger agnosia, dyscalculia, right-left disorientation and agraphia. The syndrome is rarely seen in its entirety and individual components often occur along with other parietal lobe symptoms. Bilateral tactile agnosia is occasionally seen, as are various forms of visual agnosia when the lesion lies posteriorly in the parieto-occipital region.

Non-dominant parietal lobe lesions may produce disturbed appreciation of the body image and of external space, particularly involving the contralateral side. The left limbs may fail to be recognised or may be disowned by the patient. If paralysed or hemianaesthetic, the disability may be ignored or refuted (anosognosia), a part of the body may be felt to be absent (hemisomatognosia), or in rare cases there may be phantom reduplication of body parts. Neglect of the left half of external space may show in the omission of left-sided details when drawings are copied, or in the crowding of writing into the right-hand part of the paper. Left-hand turnings may be overlooked when finding the way about. 'Dressing dyspraxia' consists of muddle when inserting limbs into garments or putting garments over the head. In addition to visuospatial agnosia there may be a marked defect of the recognition of faces (prosopagnosia) when the lesion is posterior and involves the occipital lobe.

Neurological signs indicative of a parietal lobe lesion include cortical sensory loss and the phenomena of extinc-

tion and inattention. Cortical sensory loss consists not of analgesia but of a more complex impairment of sensation and difficulty with discrimination; objects cannot be identified by palpation (astereognosis), figures written on the hand cannot be named (agraphaesthesia), two-point discrimination is impaired, and the localisation of sensory stimuli is inaccurate. Sensory extinction (sensory inattention) is shown when two parts of the body are lightly touched simultaneously and that on the side contralateral to the lesion is not perceived. Visual inattention may be demonstrated by asking the patient to point to moving objects in both half-fields of vision; when two objects move simultaneously that in the contralateral half-field is ignored.

Sensory deficits are often accompanied by evidence of mild hemiparesis in the limbs contralateral to the lesion. Deep lesions affecting the optic radiation produce a contralateral homonymous hemianopia, usually more fully developed in the lower than the upper quadrants.

Temporal lobes

Lesions restricted to the poles of the temporal lobes can be entirely asymptomatic. More commonly, however, temporal lobe lesions are associated with disturbance of intellectual functioning, lesions of the dominant lobe more so than those of the non-dominant lobe.

Dominant temporal lesions may produce language difficulties alone. This is typically a sensory dysphasia, resulting in severe cases in jargon productions. More posterior lesions on the dominant side may also impair visual aspects of language in the form of alexia and agraphia. Parietal lobe symptomatology may then also appear by way of motor apraxia, constructional apraxia and aspects of Gerstmann's syndrome.

Non-dominant temporal lobe lesions often show a paucity of symptoms and signs. Sometimes, however, visuospatial difficulties are in evidence, also prosopagnosia and hemisomatognosia.

Bilateral lesions of the medial temporal lobe structures can produce amnesic syndromes of great severity and virtually uncontaminated by other intellectual disturbances (see Chapter 2, Medial temporal amnesia). Unilateral temporal lobe lesions lead to a more restricted disturbance of memory for certain classes of material along with related perceptual deficits, but this is rarely a spontaneous complaint and is usually revealed only by special testing. Lesions on the dominant side impair the learning and retention of verbal material even in the absence of overt dysphasia. Non-dominant lesions impair the learning and retention of non-verbal patterned stimuli, such as music, or faces and drawings to which a name cannot be attached.

Personality disturbances identical with those accompanying frontal lesions may occur, but will more commonly be associated with intellectual and neurological deficits.

Chronic temporal lobe lesions are notorious for their association with disturbance of personality, and particularly with emotional instability and aggression. Similarly lesions of the temporal lobe appear to carry an increased risk of psychotic disturbances akin to schizophrenia. Depersonalisation may be prominent, also disturbance of sexual function. Epileptic phenomena are common with temporal lobe lesions and give important evidence of localisation (Chapter 6).

The most reliable neurological sign of deep temporal lobe lesions is a contralateral homonymous upper quadrantic visual field defect, caused by interruption of the visual radiation in the central white matter. This sign alone may occasionally betray the presence of a temporal lobe lesion in a dementing process that has been attributed to diffuse brain damage. Deep lesions may also result in a mild contralateral hemiparesis or sensory loss due to encroachment upon fibres in the corona radiata. Equilibrium and hearing are not impaired, even by extensive unilateral lesions of the temporal neocortex.

Occipital lobes

Occipital lobe lesions lack well-established focal symptomatology except where vision is concerned. Complex disturbances of visual recognition characterise lesions of the parastriate areas. Agnosia for written or printed material (alexia without agraphia), colour agnosia and 'simultanagnosia' are characteristic of dominant occipital or occipitotemporal lesions, whereas bilateral pathology is usually present with visual object agnosia or prosopagnosia. Visuospatial agnosia occurs more commonly from non-dominant than from dominant occipitoparietal lesions, likewise metamorphopsia in which the appearance of objects is distorted. Complex visual hallucinations are said to occur more commonly from non-dominant than dominant occipital lesions.

Lesions of the striate cortex produce homonymous defects in the opposite half-field of vision and occasionally simple visual hallucinations of patterns, flashes of light, etc. Extensive bilateral lesions may produce cortical blindness, distinguished from peripheral blindness by the normal appearance of the optic fundi and the preservation of pupillary light reflexes.

Corpus callosum

Expanding corpus callosum lesions typically extend laterally into adjacent parts of the hemispheres, producing a picture of severe and rapid intellectual deterioration along with changes specific to the lobes involved. Anterior tumours produce marked frontal lobe disturbance, often with extreme psychomotor retardation and asponaneity. Dysphasia, apraxia and asymmetrical pyramidal signs are common when the parietal lobes are affected. Involvement of diencephalic structures leads to somnolence, stupor and akinesia. Bizarre postural motor abnormalities may strongly resemble

the pictures seen in catatonia. Disruption of communication between the two hemispheres may result in lack of access of the non-dominant hemisphere to the speech mechanisms in the dominant hemisphere; there will then be left-sided apraxia to verbal commands, with agraphia and astereognosis in the left hand (Geschwind 1965). Lesions restricted to the posterior part, in association with lesions of the left occipital lobe, may result in alexia without agraphia (or pure word blindness) for similar reasons.

Diencephalon and brainstem

The most characteristic symptoms of lesions in the deep midline structures of the brain are amnesia of the Korsakoff type and hypersomnia. These may stand out against a background of progressive intellectual deterioration or present initially as the sole disturbance. Amnesia that is strikingly more marked for recent than remote events, and is sometimes accompanied by confabulation, is characteristic of lesions in the neighbourhood of the third ventricle, aqueduct and posterior hypothalamus. Somnolence and hypersomnia suggest a lesion of the posterior diencephalon and upper midbrain. It may fluctuate in intensity, or occur in brief attacks suggestive of narcolepsy. Sometimes it may progress to states of profound stupor or coma. Akinetic mutism ('coma vigil') is a characteristic syndrome in which the patient lies immobile and mute, though the eyes may be open and follow moving objects (see Chapter 6, under Diencephalic tumours).

Intellectual deterioration may occur by virtue of raised intracranial pressure consequent upon obstruction of the cerebrospinal fluid circulation. Some focal lesions, however, produce rapidly progressive dementia without such generalised disturbance, particularly those originating within the thalamus. Features closely akin to the 'frontal lobe syndrome' may occur with diencephalic and brainstem lesions: disinhibition, indifference, carelessness and euphoria. Insight into the changes is said to be better preserved than with the equivalent pictures produced by frontal lobe lesions. Swings of mood and sudden outbursts of violent emotion are also held to be characteristic. Bilateral lesions within the upper brainstem and diencephalon, seen for example with pseudobulbar palsy, are associated with extreme emotional lability and 'emotional incontinence'. The patient laughs or cries excessively in response to trivial stimuli, yet if questioned he denies experiencing the degree of emotion he displays, and may well be distressed at his inability to control the response.

Focal neurological signs may be surprisingly absent in the early stages of progressive diencephalic lesions. Raised intracranial pressure with headache and papilloedema are found with the majority of obstructive lesions, though even here mental symptoms may be severe before this develops. Visual field defects will betray lesions such as

craniopharyngiomas which grow upwards from the sella turcica and compress the optic chiasma. However, the patient who has considerable intellectual loss may make no complaint of the visual field disturbance, and testing can sometimes be impossible.

Disturbance of hypothalamic function can result in polydipsia, polyuria, hyperphagia and obesity or elevation of temperature. Amenorrhoea or impotence may occur in the adult, delayed or precocious sexual development in the child. Involvement of the pituitary gland will result in a wide variety of endocrine changes, which may, however, be overlooked for a time when psychiatric disturbance is prominent.

Thalamic lesions cause the sensory disturbances characteristic of parietal lobe lesions with, in addition, hypalgesia or analgesia to painful stimuli. Brainstem lesions cause characteristic cranial nerve palsies, along with evidence of dense long-tract motor and sensory disturbances.

Basal ganglia

Disorders of the basal ganglia are, in classical neurology, liable to present with one of the involuntary movements as their more visible manifestation. However, neuropsychiatric presentations of basal ganglia lesions are being increasingly recognised. Such lesions are commonly the result of degenerative conditions such as Parkinson's disease and Huntington's chorea and hence present with a gradually deteriorating course. By virtue of the strong reciprocal connections between the basal ganglia and the frontal lobes, many presentations have a strong 'frontal' flavour. These tend to be of the more 'negative' type, with slowing of thought, speech and movement and lack of spontaneity and motivation being most prominent. Indeed, depressive disorders are a common accompaniment as well as being a major part of the differential diagnosis. However, apathy may give way to irritability and diffuse cerebral dysfunctions. Rigid patterns of behaviour and repetitiveness may lead to frank obsessional-compulsive disorders. There is a particular constellation of

cognitive deficits that has become known as the 'subcortical dementias' (see Table 1.3 and Chapter 12).

Differential diagnosis

The correct appraisal of patients with neuropsychiatric disorders is a test of both psychiatric and general medical skills. The detailed differential diagnosis of individual conditions will be considered in the appropriate sections elsewhere, but here certain general principles are outlined.

Of first importance is the ability to distinguish between organic and non-organic psychiatric illness, in other words to recognise when identifiable brain disorder is the root cause of the presenting clinical picture. The nature of the cerebral disorder must then be determined by a process of enquiry that proceeds logically in accordance with reasonable expectations. A distinction between acute and chronic organic reactions is often helpful in deciding on probabilities, as is the distinction between diffuse or focal cerebral disorder. Thereafter the range of possible causes remains wide, and will also be briefly discussed below.

Differentiation from non-organic conditions

There can be little difficulty in deciding on an organic aetiology when impairment of consciousness or of cognitive processes is marked, when there are epileptic fits, or when psychiatric symptoms are accompanied by obvious neurological symptoms and signs. But this is not always the case. Some organic disorders can present with hallucinations, affective change or schizophrenia-like symptomatology and lack clear organic accompaniments throughout their course. Others unfold very gradually, with indefinite organic features and with symptomatology suggestive of virtually any form of psychiatric illness. Special predisposition to neurotic forms of reaction, or to psychotic illness, may confer distinctive features which for some time obscure the true situation.

Table 1.3 Characteristics of the cortical and subcortical dementias.

Feature	Cortical (e.g. Alzheimer's disease)	Subcortical (e.g. Parkinson's and Huntington's diseases)
Language	Dysphasia early	Reduced output
Memory	Recall and recognition impaired	Some impairment in recall
Visuospatial	Impaired early	Impaired
Calculation	Impaired	Preserved until late
Executive function	Normal early	Reduced, especially spontaneity and flexibility
Psychomotor	Normal early	Slowed
Abnormal movements	None (myoclonus rare)	Chorea, tremor, stooped posture, etc.
Personality/behaviour	Preserved unless 'frontal lobe'	Apathetic, withdrawn
Mood	Euthymic; may lack awareness	Depression common

The converse is also true, since patients with non-organic psychiatric illness may show features that raise the possibility of cerebral disease. For example, disorientation and minor impairment of consciousness may be detected at the onset of acute schizophrenia, also sometimes in mania and agitated depression, yet without evidence of identifiable brain malfunction either at the time or subsequently. Similarly, cognitive impairment, including difficulty with recent memory, may accompany purely affective disorders particularly in later life, as discussed in Chapter 9. Features resembling delirium, including characteristic disturbances of thought processes and even hallucinations, can occur in mania (Hutchinson & David 1997) and follow psychological stress, as in sensory deprivation or sleep deprivation. It is probable that subtle perturbations of brain function underlie all such examples, though these are not yet identifiable by routine clinical investigation; moreover, the possibility of their presence has little practical implication for treatment.

Thus it is clear that the line of demarcation between organic and non-organic psychiatric disorders is not hard and fast, and in a substantial number of cases there can be continuing uncertainty. Some commentators use this to encourage an abandonment of the organic/non-organic distinction as if it were a primitive throwback to Cartesian dualism. However, while neuropsychiatry is the embodiment of an integrated approach to mind and body, it is not an excuse for woolly thinking or for ignoring the very real distinctions between classes of disorder. These distinctions remain valid and useful in practice for the great majority of cases. The margin for error is reduced when investigations are undertaken, but even so is not removed completely. Specialist investigations such as electroencephalography (EEG), psychometric testing, radiographic procedures and functional brain imaging techniques may all be helpful but can be equivocal and even misleading. It is important to remember that the more sensitive the technique, the more likely it is to yield false-positive results. Clinical examination therefore remains of the first importance, and is in any case the chief guideline that determines whether or not special investigations should be undertaken. Examples of patients in whom unusual problems in the differentiation between organic and non-organic disorder have arisen, often with surprising results, have been described by Lishman (1992).

Neurotic disorder may be simulated in the early stages of cerebral disease by virtue of diffuse complaints of anxiety, depression, irritability and insomnia. The patient may himself complain of forgetfulness and difficulty in concentration, but these tend to be discounted because of the multitude of other vague somatic symptoms. Involuntary movements, tremors and akathisia may be put down to simple anxiety. Phobic and obsessional symptomatology is not uncommon at the onset, and may remain a prominent feature for some considerable time. It is also well known that

one must be wary of neurotic developments beginning only in middle life and when the previous mental constitution was good, also to seek for clear evidence of adequate immediate causes for their appearance.

Sometimes the clue may lie in the patient's attitude towards his symptoms. The organic patient will often tend to play down his deficits so that a graver picture is obtained from relatives than from the patient himself. The neurotic patient, by contrast, presses home his symptoms and actively seeks a remedy for them. The patient's evasiveness may raise suspicion, or when pressed he may display abrupt 'catastrophic' reactions of distress or anger. Typically also the organic patient's symptomatology lacks the richness and diversity seen in purely neurotic disorders.

Conversion ('hysterical') disorder may also be simulated by organic conditions. Acute organic reactions tend to fluctuate with periods of lucidity, and symptoms may thus be fleeting. A shallow affective quality and a tendency to make light of symptoms may suggest the *belle indifférence* of hysteria. In mild delirium the cardinal features of impairment of consciousness and subtle deficits of attention may sometimes be hard to determine, and behaviour may be seemingly motivated for display. Thus it may be necessary to watch closely for signs of perseveration, slight dysarthria and other minimal features that betray the organic basis of the disorder.

Episodes of bizarre behaviour in hypoglycaemic attacks, or of paralysis in porphyria, provide well-known diagnostic hazards in which conversion disorders come to be suspected. Similar difficulty is sometimes found with periods of long-continued abnormal behaviour following encephalitis. Frank conversion symptoms may of course occur with chronic brain disease and be mistaken for the primary disorder. It is unclear how far these reflect in some way the direct effects of cerebral damage, or how far they merely represent a psychogenic response to the patient's partial awareness of his deficits. Again, it is axiomatic to view with grave suspicion 'hysterical' symptoms that make their first appearance only in middle life. The problem of the differential diagnosis of pseudodementia is discussed in Chapter 9.

Schizophrenic symptoms in association with cerebral disease can readily be misleading. A preponderance of visual over auditory hallucinations should raise suspicion of an organic disorder, similarly an empty or shallow affective colouring to delusional beliefs and passivity phenomena. Delusions in both acute and chronic organic reactions may take any of the forms seen in schizophrenia, but paranoid delusions are by far the most common. Certain qualities of the delusions strongly suggest an organic basis, namely those which are vague, poorly systematised, incoherent, fleeting and changeable, or restricted and stereotyped in content. Nevertheless, schizophrenic illnesses that are typical in every respect

occasionally prove ultimately to be founded on identifiable cerebral disease. Disorders of the temporal lobes are the most likely to present with schizophrenia-like features.

Depressive symptoms can also give rise to difficulty. Ordinary affective disorder can be associated with marked slowness of thinking, difficulty with concentration and uncertainty with memory. There may be considerable doubt about the correct evaluation of such features, and psychometric testing may give equivocal results. The difficulties are increased when electroconvulsive treatments have already been given.

Features that may help in distinguishing primary depressive illness from organic psychiatric disorder include the careful appraisal of the setting in which disturbances of concentration and memory occur. In depressive illness it can often be observed that lack of interest or excessive anxiety prevent the focusing of attention on the matter in hand, rather than any pervasive difficulty with the organisation of thought and memory. Preoccupation with morbid thoughts may operate similarly. Typically the patient with uncomplicated depression is able to give a more coherent account of his discomforts and a more accurate chronology of his illness than would be possible in the presence of cerebral disease. These important aspects of differential diagnosis are considered more fully in the section on depressive pseudodementia (Chapter 9).

Personality disorder is especially liable to be suspected where frontal lobe dysfunction is concerned, for example following injury or in the early stages of a frontal dementia. Irresponsible behaviour or lapses of social conduct may be attributed to pre-existing personality factors, particularly when there has been some recent stress or problem in the patient's life. Here the essential clue will lie in a careful history from an informant which reveals the change that has occurred. Other avenues to the differential diagnosis are less reliable. Thus the patient may fail to display the classic features of frontal lobe disturbance at interview. And psychometric testing cannot always be relied upon in making the distinction; cognitive ability may be well preserved, and even tests specially devised to reveal frontal deficits can occasionally be misleading. Examples of frontal tumours or chronic infections presenting with change of disposition and behaviour are described in Chapter 2. Functional neuroimaging is increasingly being used to investigate the possibility of focal and generalised cerebral disorders presenting diagnostic difficulties. Frontal lobe dementia is described in Chapter 9. Special difficulty will of course arise in patients whose personality has always been abnormal.

Differentiation between acute and chronic organic reactions

In practice this distinction is most directly made from the history of the mode of onset of the disorder. A short history and firm knowledge of an acute onset will make a chronic

organic reaction unlikely. Onset in association with a physical illness rather strongly suggests an acute organic reaction. However, when such leads are lacking close attention to phenomenology may be necessary.

Acute rather than chronic cerebral disorder is suggested when there are severe perceptual disturbances and distortions, with prominent illusions and hallucinations in the visual modality. Defective appreciation of reality may lead to rich and intrusive fantasies, in contrast to the emptiness and impoverishment of thought characteristic of chronic organic reactions. Similarly, in the presence of florid behaviour disturbance, this will be seen to be dictated by disturbed thought processes of a more sophisticated kind in acute than in chronic cerebral disorder. The affective state of the patient may also help with the distinction. In acute organic reactions the emotional disturbances are typically of a positive kind – fear or terror, perplexity and agitation – whereas the demented patient may be flat, apathetic and emotionally unresponsive. Emotional rapport can usually be established in patients showing clouding of consciousness, but tends to be poor in dementia.

This said, it must be recognised that in practice the differentiation between acute and chronic organic reactions can sometimes be very difficult. Despite careful observation, the distinction may come to be revealed only by the time course that is followed. For example, a prolonged subacute delirious state due to anoxia, uraemia or hepatic disorder can simulate dementia very closely. Or the patient may be admitted to hospital without a history to point to the acute and recent onset of the disorder. Perhaps most difficulty is encountered with elderly patients who show postoperative disturbances, due to metabolic derangements or anoxia, and in whom the mental state was incompletely evaluated beforehand. The electroencephalogram may provide some guidance in such examples (see Chapter 3, under Electroencephalography). The distinction between delirium and dementia may be aided by a simple list of contrasting features compiled by Butler and Zeman (2005) (Table 1.4).

Differentiation between diffuse and focal lesions

Symptoms and signs of localising significance must be carefully sought in all organic psychiatric disorders, and when discovered must not be ignored. Local disturbances of cerebral function can, of course, occur with progressive cortical disease before it is sufficiently extensive to produce a global dementia; well-known examples are a circumscribed amnesic syndrome in the early stages of Alzheimer's disease or a frontal lobe syndrome in Pick's disease (see Chapter 9). Evidence of focal brain damage may also emerge later in the course of such disorders when the pathological changes become especially advanced in certain regions of the brain. Signs of focal damage must therefore be carefully assessed in relation to the clinical picture as a whole, but will usually dictate that further investigations should be under-

Table 1.4 Delirium versus dementia. (From Butler & Zeman 2005.)

Feature	Delirium	Dementia
Onset	Abrupt/subacute	Insidious
Course	Fluctuating	Slow progression
Duration	Hours to weeks	Months to years
Alertness	Abnormally high or low	Typically normal
Sleep–wake cycle	Disrupted	Typically normal
Attention	Impaired	Relatively normal
Orientation	Impaired	Intact in early dementia
Working memory	Impaired	Intact in early dementia
Episodic memory	Impaired	Intact in early dementia
Thought	Disorganised, delusions	Impoverished
Speech	Slow/rapid, incoherent	Word finding difficulty
Perception	Illusions/hallucinations common	Usually intact in early dementia
Behaviour	Withdrawn/agitated	Varies: often intact early

taken. The important problem is to distinguish the essentially focal lesion from diffuse brain damage, because a remediable cause may then come to light. Finally, the neurological examination should always be supplemented by careful enquiry and observation for epileptic disturbances of focal origin.

Psychological symptoms of possible localising value include amnesia out of proportion to other cognitive deficits, dysphasia, somnolence, and the several aspects of parietal lobe symptomatology that have been discussed above. Mild dysphasia due to focal cerebral disease may be mistaken for early dementia when the patient's account is hesitant and incoherent, or when he is anxious and depressed as a result of his disability. However, careful observation usually shows that behaviour not involving language remains substantially intact. Dysphasic difficulties, and especially nominal dysphasia, may be seen with diffuse cerebral disorder, but then insight into the defect is less likely to be well preserved. Agnosic and apraxic deficits, and disturbances of the body image and of spatial orientation, likewise raise suspicion of focal cerebral disorder when severe and out of all proportion to other cognitive difficulties. Such deficits are, however, relatively common in acute organic reactions or when consciousness is impaired to a significant extent, and when chronic diffuse brain disease has progressed beyond the early stages.

Special investigatory procedures, as outlined in Chapter 3, are the most reliable arbiters in the distinction between focal and diffuse brain damage, and will often need to be undertaken before a firm differentiation is achieved.

Causes of acute and chronic organic reactions

The specific cause in the majority of cases will readily become apparent in the course of history-taking and examination. In

many it is self-evident from the outset. Sometimes, however, the cause may be elusive and it is then essential to consider systematically a wide range of possibilities. These are shown in Tables 1.1 and 1.2.

It is helpful in approaching a given case to consider first the possible causes arising within the CNS itself, then derangements of cerebral function consequent upon disorders in other systems of the body. This division is reflected approximately in the ordering of causes in Tables 1.1 and 1.2. Even some of the very rare conditions are remediable, and enquiry must therefore be extensive when the solution is not soon forthcoming.

The antecedent history will give important clues, and it is essential that a relative or close acquaintance should be seen. The time and mode of onset must always be carefully established. The classic presenile and senile dementias usually begin insidiously and their history commonly extends over several months, whereas remediable illnesses often have an abrupt and relatively recent onset. Careful enquiry should always be made for a history of head injury, fits, alcoholism, drug abuse, recent illness or anaesthesia. Even in the absence of known head injury the possibility of subdural haematoma should be kept in mind, since this may follow trivial injury in arteriosclerotic subjects or be forgotten in alcoholics. It may be followed by a latent interval, and be accompanied by minimal neurological signs. A known epileptic tendency may suggest that the present disturbance is an unusually prolonged complex partial seizure or postictal state. Fits of recent onset may indicate a space-occupying lesion, or some acute cerebrovascular accident or injury that has left a residual focus of brain damage. A history of alcoholism or drug abuse may be long concealed in some cases, even on occasion by relatives as well as by the patient. Suspicion may only be raised by indirect evidence from the patient's attitude to enquiry or unwillingness for hospitalisation. A history of

repeated episodes over a considerable period of time may strongly suggest that drug abuse is responsible.

Apart from self-administered drugs, it is always important to enquire about medication recently prescribed. This may have contributed by way of toxic effects, idiosyncratic reactions or the lowering of blood pressure. Diuretics given without proper supervision may have led to electrolyte depletion. If the patient is a known diabetic, enquiry must be made about previous hypoglycaemic reactions, the current dose of insulin and the current diet. The list of drugs that can affect cognitive functions is almost limitless and idiosyncratic reactions are always possible. Hence a high index of suspicion is required. A useful update on medications with propensity to cause neuropsychiatric effects is provided by Turjanski and Lloyd (2005).

A history of recent illness and operation should be noted, and also the quality of recovery from any recent anaesthetic. Previous episodes of dysphasia, paralysis or other neurological deficit will be suggestive of cerebral arterial disease. Any indications that the patient may be at risk of HIV infection should be noted, also a family history of illness such as Huntington's disease.

In patients with acute organic reactions it is still important to enquire for an antecedent history of failing memory or intellect over some period of time, since an incipient chronic dementia may be being aggravated by intercurrent disease. The adequacy of diet should be assessed in elderly patients, especially when living alone, or in patients of low intelligence and low economic means. Vitamin depletion is certainly not excluded in patients suffering from presenile or senile dementing illnesses and may be adding to the disability. Finally, in the more immediate history, specific enquiry should always be made for headache, vomiting or visual disturbance indicative of raised intracranial pressure, and in Elderly patients for breathlessness, ankle swelling or substernal pain which may indicate recent cardiac decompensation.

On examination one must pay attention to any appearance of physical ill health which may be token metabolic disorder, carcinoma or an infective process. The general appearance of the patient may indicate anaemia, or an endocrine disorder such as myxoedema that is otherwise easily missed. Dehydration may suggest uraemia or diabetic precoma. Muscular twitching suggests uraemia, electrolyte disturbance or hypoglycaemia. There may be skin lesions diagnostic of exanthemata or indicative of vitamin deficiency. It may be necessary to search closely, by 4-hourly temperature recording, for evidence of low-grade intermittent pyrexia indicating, for example, encephalitis or cerebral abscess. Finally, very careful general observation may sometimes reveal the choreiform movements diagnostic of early Huntington's chorea.

Examination of the CNS must pay careful attention to the optic fundi for signs of raised intracranial pressure, to abnormalities of pupil size or reactions indicative of syphilis, or

nystagmus which may suggest drug intoxication. Transient disorders of external ocular movement may be the essential sign for confirming a diagnosis of Wernicke's encephalopathy. Evidence of focal neurological defects in motor or sensory systems (including unsuspected visual field defects) will suggest a space-occupying lesion or cerebrovascular disease. Neck stiffness may indicate subarachnoid haemorrhage or meningitis, and evidence of recent ear infection will raise the possibility of cerebral abscess.

Signs of arteriosclerosis should be noted both at the periphery and in the optic fundi. The patency of the carotid arteries should be tested by palpation and auscultation in the neck. Hypertension must be assessed, likewise evidence of cardiac failure, heart block or recent coronary infarction. Respiratory infection or inadequacy must also be noted as possible causes of cerebral anoxia. Even in the absence of hepatic or splenic enlargement it may be necessary to examine for liver flap, spider naevi or fetor hepaticus. It can be important to examine for prostatic enlargement. Carcinoma with secondary cerebral deposits, or secondary 'remote' effects upon the CNS, may need to be excluded by palpation of breasts, neck, axillae, and rectal and vaginal examinations. A chest X-ray will be obligatory for exclusion of carcinoma of the lung.

Investigations in every case should include haematology, erythrocyte sedimentation rate, blood urea, serum electrolytes and proteins, liver function tests, serum thyroxine, estimation of blood sugar, serological tests for syphilis, urine examination and chest radiography, no matter what may appear to be the cause. Skull radiography and EEG may be required, and computerised tomography (CT) or magnetic resonance imaging (MRI) will quite often be undertaken. It may be necessary to proceed with estimation of serum B_{12} and folate, or urinary examination for drugs or evidence of porphyria. An electrocardiogram may be indicated if silent myocardial infarction or Stokes-Adams attacks are suspected, along with other cardiovascular specialist investigations such as echocardiography, Doppler studies of the carotid arteries and coagulation screens. Immunological tests for autoantibodies and paraneoplastic markers may be valuable. The problems surrounding HIV testing and the need to obtain informed consent beforehand are discussed in Chapter 7. Lumbar puncture will sometimes be required when the diagnosis remains in doubt, in particular to confirm suspicions of intracranial infection. Further investigations such as a radioisotope scan or angiography will sometimes be indicated, though CT and MRI have greatly reduced the need for these.

Causes of stupor

Mention may be made of the differential diagnosis of stupor. The causes may be organic or non-organic, and the differential diagnosis must embrace schizophrenia, depression and hysteria in addition to organic brain dysfunction.

Joyston-Bechal (1966) examined the records of 100 cases of stupor diagnosed at the Bethlem Royal and Maudsley Hospitals in order to obtain an indication of the frequency of different causes. In this setting organic causes are seen in one-fifth. The essential features of the stupor were closely similar in the organic and non-organic cases. In 14 cases, the cause remained uncertain. Sometimes the true situation was unclear at the time of the patient's presentation, but was revealed in retrospect when the stupor had resolved. A more recent series (Johnson 1984) had twice the prevalence of 'organic' cases. This may reflect advances in diagnostic techniques, especially non-invasive neuroimaging. In Joyston-Bechal's (1966) series almost half of the stupors resolved within a week, and only one-fifth lasted more than a month. The six patients who remained in stupor for more than 6 months were all severely brain damaged.

Knowledge of the antecedent psychiatric history is often invaluable in suggesting the cause, and a careful neurological examination is always essential with special attention to signs that may indicate a diencephalic or upper brainstem lesion (see Diencephalon and brainstem, earlier in chapter). Patients with stupor due to non-organic psychiatric illness are more likely to show some partial preservation of ability to help with feeding or eliminative functions, though this is by no means invariable. The facial expression and posture is also more likely to be meaningful or show some emotional reaction to what is said or done. On recovery, patients with non-organic stupors often prove to have retained awareness of what transpired during the episode, whereas in organic stupor the level of awareness as well as the level of responsiveness is usually severely diminished.

Schizophrenic stupor is mainly a catatonic phenomenon, and is usually seen along with other catatonic features such as negativism, echopraxia, posturing or *flexibilitas cerea*. It tends to carry a poor prognosis in the long term. The patient's posture is often fixed and bizarre, and may have symbolic meaning in connection with his delusions. When disturbed the special posture is often resumed. The facial expression may be secretive or withdrawn, and may betray attention to hallucinatory experiences. Some schizophrenic stupors appear to represent withdrawal into a world of delusional fantasies, whereas in others it seems that nothing at all is experienced by the patient. The latter may represent a prolongation in severe form of schizophrenic blocking of thought and of willed action. After acute treatment with, for example, lorazepam or electroconvulsive therapy (ECT), some patients may dramatically recover and may then be able to explain that their immobile state was a response to beliefs or hallucinatory injunctions. In other cases the patient apparently has no recollection of the episode. An important diagnosis to consider is neuroleptic malignant syndrome, an idiosyncratic response to many antipsychotic drugs (see Chapter 11); regardless of cause, some authorities advocate ECT as an effective treatment (Fink & Taylor 2001).

Depressive stupor may occasionally be just as profound as the above, and the differentiation can be difficult if the antecedent psychiatric history is unknown. Usually it can be seen to develop out of severe psychomotor retardation, which increases until there is universal motor inhibition. The posture and expression are sometimes indicative of sadness and hopelessness, and silent tears may be shed. Sometimes, however, the expression is apathetic and vacant. Conscious awareness is usually fully retained and the patient can later relate most of what was said and done to him.

Manic stupor is usually described as uncommon. The expression may be of elation or ecstasy, and the patient may later report that his mind was filled with teeming ideas to the extent that he was unable to react to anything around him. Surprisingly, in Abrams and Taylor's (1976) prospective study of catatonic patients, mania emerged as the commonest diagnosis, applying also to the subgroup who had shown stupor.

Hysterical and psychogenic stupors usually occur in a situation of stress, and manifest superficial motives can often be discerned. Signs of conversion hysteria are commonly in evidence. The condition is more likely than others to wax and wane, and there may be a marked emotional reaction when sensitive subjects are discussed. Completely passive dependence on others for feeding and toilet functions is rare, and the patient may show signs of irritability and annoyance when moved against his wishes.

Organic stupor has many causes, the most urgent of which is raised intracranial pressure producing a medullary or midbrain pressure cone. Focal pathologies in the region of the posterior diencephalon or upper midbrain include tumours (especially craniopharyngiomas), infarctions, meningitis (especially tuberculous meningitis), neurosyphilis and formerly encephalitis lethargica. Senile or presenile dementias may lead to stupor late in their course, likewise HIV-associated dementia. Complex partial seizures may take this form, or alternatively stupor may follow briefly in the wake of an epileptic seizure.

When a brain lesion is responsible for stupor, the site will commonly lie in the upper brainstem or mesencephalon. Sometimes, however, it is due to involvement of the antero-medial frontal lobes and adjacent septal area (Segarra 1970). With stupors of brainstem origin the patient tends to be apathetic and somnolent most of the time and will frequently show pareses of external ocular movement. Patients with frontal stupor are more likely to appear alert, ready to be roused and with seeming vigilant gaze (hyperpathic akinetic mutism). Lesions of the anterior cingulate and its subcortical connections seem to be implicated (Mega & Cohenour 1997).

Extracerebral causes that must be considered include a number of the conditions listed in Table 1.1. Pictures typical of stupor may occasionally be seen with uraemia, hypoglycaemia or liver disorder, or postoperatively with electrolyte

disturbance or water intoxication. Endocrine disorders include myxoedema, Cushing’s disease, Addison’s disease, hypopituitarism and hyperparathyroidism. Stupor may also emerge with severe alcoholic intoxication, other intoxications, nicotinic acid deficiency encephalopathy, or terminally with certain infections such as typhus fever. It is important to remember that it can occasionally be seen as an adverse reaction to psychotropic medication; in Johnson’s (1982) series of 25 cases, two were due to intoxication with lithium and one to excessive medication with flupenthixol. The neuroleptic malignant syndrome in either its full-blown or partial form should also be considered in any person exposed to antipsychotic drugs presenting with stupor and abnormally increased muscle tone. The presence of pyrexia and a raised creatine phosphokinase level form part of the diagnostic criteria.

Fortunately, with the great majority of organic causes there will be evidence of neurological dysfunction or systemic disturbance. In equivocal cases the EEG is often helpful in deciding between a psychiatric or a neurological aetiology. The absence of alpha rhythm and reduced reactivity is expected while faster rhythms may indicate a toxic or drug-induced state. Triphasic waves may be seen in hepatic and renal insufficiency in young adults and spindle coma patterns are believed to indicate brainstem dysfunction; the EEG may reveal previously unsuspected non-convulsive status epilepticus (Kaplan 2004). When psychogenic causes are suspected, an interview under Sodium amytal or a benzodiazepine may confirm the situation, while in schizophrenic and depressive stupors the response to ECT can be dramatic.

Causes of mutism

Mutism is rarely an isolated phenomenon, often occurring along with catatonic signs such as negativism, stereotypy, posturing or stupor. It may therefore be associated with the several psychiatric conditions discussed above. Important organic causes include head injury, posterior fossa surgery, encephalitis, frontal lobe lesions, the postictal phase of epilepsy, and endocrine disorders including hyperparathyroidism, myxoedema, diabetic ketoacidosis and Addison’s disease (Gordon 2001). Complete speechlessness is rare in aphasic disorders since there is frequently some attempt to communicate or vocalise. The exception is the end stage of frontotemporal dementia.

Mutism without catatonic features may also be due to organic or non-organic causes. Dissociative states are among the commoner associated conditions, though here it is essential that severe dysphasia is excluded, as outlined in Chapter 2, Conversion disorders. In younger people, elective mutism is a relatively common reaction to a range of emotional disturbances and social anxiety.

Altshuler *et al.* (1986) drew together collected series of patients presenting with mutism and attempted to assess the

Table 1.5 Causes of mutism. (After Altshuler *et al.* 1986.)

All causes		Organic causes	
Schizophrenia	6	Stroke	4
Schizoaffective disorder	2	Postencephalitic disturbance	2
Other psychosis	1	Organic affective disorder	2
Affective disorder	3	Organic delusion syndrome	1
Organic disease	10	Phencyclidine psychosis	1
Total	22	Total	10

frequency of various causes. The pooled results showed that some 40% were likely to have affective disorder, 30% schizophrenia, 9% personality disorder and 17% an organic cerebral cause. In the remainder the responsible factors were uncertain. The diagnoses in these authors’ own series of 22 patients presenting over a 2-year period are shown in Table 1.5; 14 of these had shown additional catatonic signs but eight had presented with mutism alone. Not uncommonly organic causes had been overlooked initially, for example in a patient with stroke who was first diagnosed as having hysterical aphonia, and in a patient with herpes encephalitis who was first thought to have catatonic schizophrenia. This emphasises the importance of careful neurological examination in every case.

Features stressed by Altshuler *et al.* as important in pointing to a neurological cause include irregular respiration, abnormal pupil responses, roving eye movements, facial weakness and an exaggerated jaw jerk. A psychiatric cause is suggested in patients who resist eye opening. Occasionally patients with a primary psychiatric disorder may be induced to whisper or communicate in writing, though the latter may also occur with infarctions leading to pure word-dumbness as described in Chapter 2 (Pure word-dumbness). The presence of accompanying catatonic phenomena cannot be relied upon as aiding the distinction between organic and non-organic causes. Again, however, an abreactive interview can often be informative.

Neuropsychology in Relation to Psychiatry

Anthony S. David and Michael D. Kopelman

Institute of Psychiatry, King's College, London

Historical and conceptual background

Neuropsychology is the branch of psychology concerned with the relationship between the brain, behaviour and thinking (cognition). The relationship is reciprocal in the sense that we understand the brain through its manifestations in psychology, including behaviour and cognition, and we gain an understanding of behaviour and cognition through the actions of the brain. The twin observations that perturbations to the brain may lead to predictable effects on its output and that the path from disturbed cognition and behaviour leads back to the brain and its functions form the cornerstone of neuropsychology. Such observations also serve to highlight the clinical underpinnings of the field even at its most academic. Indeed the founding fathers of neuropsychology were invariably clinicians whose area of practice approximated that of the modern neuropsychiatrist.

Certain psychological manifestations deserve particular attention because they are sometimes found in association with relatively circumscribed brain lesions. In every case they can also be seen with pathology which involves the brain diffusely or disturbs its functions widely, so their presence is by no means a certain indication of a single localised lesion. Nevertheless, when they emerge as isolated defects or stand out prominently against a background of mild impairment of other cerebral functions, they command especial care in the search for focal pathology.

What we ask of psychological symptoms as guides to focal pathology must be considerably less than we expect of neurological signs. The latter will often point with fair precision to the site of the lesion, but psychological symptoms can often tell us little more than that the pathology is unlikely to be diffuse. The careful analysis of dysphasia or of visual perceptual deficits may take us some way towards assessing the site of the lesion, but even here we must usually be content

with rather broad indications of the areas of brain that fail to function. Thus with rare exceptions there remains uncertainty about the 'regional' as opposed to the 'focal' implications of most of the syndromes considered in this chapter. Some of them will be found to owe their origin, in different patients, to focal lesions in a variety of sites.

The majority of focal psychological symptoms represent defects of cognitive functioning. Less can be said with certainty about the focal significance of emotional, motivational or 'personality' abnormalities. 'Psychotic' symptoms, with a few exceptions, elude clear ties to focal brain pathology, and here other determinants are known to be more important. Nevertheless, certain non-cognitive disorders and even some psychotic manifestations do show interesting regional affiliations, and these will also be briefly reviewed.

Strictly focal brain damage or dysfunction is rare, except when produced by operations on the brain. In naturally occurring disease we see merely a focal emphasis in pathology, with effects that are then compounded by the effects of damage elsewhere. Focal head injury, for example, is usually accompanied by brain damage remote from the site of principal destruction; epileptic disturbances which originate focally disrupt other cerebral systems more or less widely; and circumscribed tumours produce distant effects by distortion of brain tissue, vascular complications or raised intracranial pressure. It is not surprising therefore that knowledge of regional cerebral disorder has been slow to accumulate and raises many areas of controversy. Brain imaging by computerised tomography (CT) or magnetic resonance imaging (MRI), and the more recent development of sophisticated functional imaging techniques, now hold promise of clarifying some of the problems in this area. Converging evidence from work with animals, experimental studies on healthy volunteers, simulations using mathematical and computer models and so forth have elevated research in neuropsychology to a key position in relation to medicine

and psychiatry, rivalling in importance and excitement the unravelling of the genetic code.

While neuropsychology is a relatively young discipline, beginning in earnest around the mid-nineteenth century, its conceptual basis dates back to Hippocrates (c.425 BCE) and the doctrine that:

the source of our pleasure, merriment, laughter, and amusement, as of our grief, pain, anxiety and tears is none other than the brain. It is specially the organ which enables us to think, see, hear and to distinguish the ugly and the beautiful, the bad and the good, the pleasant and unpleasant.

And as for neuropsychiatry, he goes on:

It is the brain too which is the seat of madness and delirium, of the fears and frights which assail us . . . it is there where lies the cause of insomnia and sleep-walking, of thoughts that will not come, forgotten duties and eccentricities (quoted in Marshall and Gurd 2003).

Cerebral localisation

The paradigm shift came with the assertion that a particular part of the brain was the 'seat' of a particular psychic function, in this case articulate language. This is usually attributed to French neurologist Paul Broca in 1861, although some claim precedence for Marc Dax nearly 30 years earlier. A constant battle has run through neuropsychology ever since between those pursuing the 'localisationist' view and those with a more holistic view of brain functions, later termed 'equipotentiality' by Karl Lashley in the early part of the twentieth century. Such battles continue to the present day. Holistic views of brain function fitted well with early humoral theories of the mind and appeared to be upheld by the early experiments on pigeons by Flourens (1824) in the first part of the nineteenth century. Strict localisationist views gained impetus during this period from the widespread credibility accorded to Franz Joseph Gall and his followers. Gall initially proffered a sophisticated view of the modular nature of brain functions but lost credibility through the doctrines of phrenology, which ultimately reached the fantastic lengths of claiming cerebral centres for such functions as 'hope', 'patriotism' and 'attraction to wine'. Lashley's work specifically addressed acquisition of knowledge. In tests of maze learning in rats, it was shown that the size but not the location of the lesion was related to impairment of learning. Lashley's law of mass action expressed the view that learning ability is determined by the total mass of normally functioning cortex.

Since the end of the nineteenth century, there has been a steady though far from smooth accumulation of evidence concerning the cerebral representation of language and of other symbolic 'gnostic' functions. Unfortunately, much of this initially depended on uncritical compilations of case material, and at the turn of the century the 'diagram makers'

were frequently in confusion. Hughlings Jackson's (1869) theory of *levels* of functional organisation within the nervous system, and the emergence of symptoms by a process of dissolution of such levels, received little attention at the time but has a strikingly contemporary ring, for instance in the classification of psychiatric symptoms as positive versus negative (or deficit) and the discussion of 'release' phenomena such as hallucinations. One of the issues is that strictly focal damage is rarely seen, and usually the lesion touches on several zones and damages several overlapping systems together. Moreover, the plasticity of organisation is such that the structure of a psychological function may vary with the particular mental task involved; for example the recall of one series may utilise a mnemonic logical path, and the recall of another series a path based on visual images. Finally, a clear distinction must always be maintained between the localisation of the pathology accounting for symptoms, and the localisation of the functions whose disturbance the symptoms represent.

Despite these necessary warnings, the careful description and experimental exploration of cases with discrete damage or highly specific deficits has led to genuine leaps in conceptual knowledge. This approach – with its emphasis on dissociations of function (i.e. the presence of a pattern of intact abilities and surprisingly marked impairments in an individual) or, even more informative, the contrasting patterns of intact abilities and marked impairments across individuals (the double dissociation) – has proved decisive in neuropsychology (Shallice 1988; McCarthy & Warrington 1990). For example, discrete lesions in the hypothalamic-diencephalic region, or damage restricted to the hippocampal areas as in the case of the patient H.M. (see Medial temporal amnesia, later), may virtually abolish new learning in any modality. Thus, contra Lashley, we now have clear evidence that the proper organisation of memory functions involves to some considerable degree discrete systems within the human brain. Finally, the search for focal deficits has also been extended into matters other than cognitive function. In animals, focal brain lesions can lead to dramatic changes of temperament (rage reactions or placidity) depending on the site of the lesion. The amygdala has been the focus of much research in this regard. And what of higher functions still such as 'personality' and social behaviour? Certainly in monkeys interesting results can follow focal extirpations of brain tissue. Such demonstrations continue to influence our understanding of emotional disorders in neuropsychiatry but with the advent of *in vivo* techniques of neuroimaging, less reliance need be placed on this type of animal experimentation.

An alternative to strict localisationism emerged in the early part of the twentieth century: the postulation of brain *systems* rather than discrete regions dedicated to functions. An early influential example is the 'circuit' described by Papez (1937) of the limbic system, which he thought constituted an essential mechanism for the elaboration of emo-

tional experience and emotional expression. More recently, Alexander *et al.* (1990) have mapped another system or rather series of circuits that links the basal ganglia and thalamus to the frontal cortex, from which may be derived the basic architecture for motor control, initiation and inhibition of action and which is believed to be affected in tic disorders, obsessive-compulsive phenomena and regulation of affect. The implication is that lesions interrupting the anatomically distributed circuit at any point may result in a rather similar clinical picture.

Other groupings or organising principles that are supralocal include the division between the left and right cerebral hemispheres. As noted the close affiliation between the left hemisphere and language was part of Broca's original insight and attempts have been made to characterise the left and right hemispheres broadly in terms of a verbal/non-verbal processing. This dichotomy had to broaden to take account of accumulating evidence for, in particular, a greater range of specialised functions localised in the right hemisphere (including language related) and non-linguistic functions of the left, giving rise to other contrasting pairings, for example analytic-holistic, serial-parallel, general impersonal-specific personal, but none has achieved universal acceptance. A boost to the notion of lateralisation of cerebral functions came with the description of the disconnection syndromes, both naturally occurring and induced by surgical transection of the corpus callosum and cerebral commissures (Geschwind 1965; Bogen 1985). These syndromes accentuate functional specialisation but also, by definition, show how patterns of deficits and preserved abilities can arise through the disruption of pathways that convey information between specialised areas of the brain rather than disruption to the areas themselves.

Despite these fascinating debates regarding the basis of neuropsychological deficits, it is disturbed social behaviour and awareness that are at the root of the presenting complaints that dominate neuropsychiatric clinical practice. A recurring question is whether these can be localised to a part of the brain. If the favoured answer is 'yes', then the candidate region is usually the frontal lobes, as discussed briefly in Chapter 1 (and see Executive (frontal lobe) syndromes, later in this chapter). From a contemporary cognitive neuroscience point of view, the frontal lobes represent the greatest challenge. The current notion is that the frontal lobes subserve (with other parts of a network) a collection of executive functions, for example willed intentional action, inhibition of pre-potent responses, selective attention, set-shifting, working memory (holding and manipulating information online), reasoning and self-awareness and possibly 'general intelligence'. The 'executive' metaphor is intended to convey the idea that such higher-level functions arise through the coordinated and controlled activity of subsidiary functions rather than the higher functions themselves being localisable within the frontal cortex or other region (see Neuropsychology of executive function, later for discussion).

This would explain the myriad disparate manifestations of neuropsychiatric disorders found to be associated with disease or dysfunction of the frontal lobes. Finally, the unthinking tendency to attribute all that is interesting and unique about human behaviour to the frontal lobes in the misguided belief that this is in some way an explanation must be resisted (David 1992).

Modern neuropsychology

Many contemporary neuropsychological theories were anticipated by the so-called 'diagram-makers' of the late nineteenth century (Shallice 1988), but the inevitable limitations of their clinical data meant that their views came to be dismissed. The term 'neuropsychology' is often attributed to Hebb (1949) whose classic *The Organization of Behaviour* was subtitled *A Neuropsychological Theory*. However, Bruce (1985) pointed out that the word had a much earlier currency. Bruce attributed the word to Osler (1913) in an address at the Johns Hopkins Hospital, subsequently published. Bruce speculated that Lashley may have attended this address; Lashley's own first use of the term appears to have been in 1936, and he was appointed Research Professor of Neuropsychology at Harvard in 1937.

The huge growth of neuropsychology after the Second World War had, perhaps, three main sources. The first was the influence of Hebb's classic book, which drew ideas from many disciplines into a unified theory and anticipated many contemporary notions. The second was the excellent series of investigations of soldiers injured by penetrating missile wounds in the Second World War, which considerably advanced our knowledge of functional localisation (and its limitations); parallel studies occurred in the UK (Newcombe 1969), the former USSR (Luria 1964) and the USA (Semmes *et al.* 1963; Teuber 1962). Thirdly, Milner's pioneering studies of H.M. (Scoville & Milner 1957; Milner 1966) demonstrated in a dramatic fashion the devastating effects of circumscribed brain pathology, and the ways in which these could be investigated by detailed experimental techniques.

A very important consequence of this burgeoning interest was the founding of the journals *Neuropsychologia* and *Cortex*, both in 1963. The International Neuropsychological Society was formed in 1967. But there were limitations to empiricism across large patient groups, and the more theoretical approach of Elizabeth Warrington, her collaborators and successors in the UK produced important advances in our knowledge of topics such as amnesia, the acquired dyslexias, semantic memory and executive function. The intensive investigation of single cases to develop or refute cognitive models that were not that dissimilar from those of the 'diagram-makers' culminated in the foundation of the journal *Cognitive Neuropsychology* in 1984, exemplifying this approach. However, despite the enormous advances made

in theoretical knowledge, there were always limitations to this approach, principally a tendency to over-generalise from the particular case and a failure to take account of other factors ('associations') that might be just as important in understanding cognitive performance as the identification of 'dissociations' in single cases. However, what seems most to have undermined the predominance of the 'single case' approach has been the requirements imposed by functional neuroimaging studies.

Current debates concern the relationship of findings from functional neuroimaging, which identify circuits recruited in association with cognitive performance, and lesion studies, which identify sites critical to a cognitive function. Debate continues about whether functional imaging studies can truly contribute to cognitive neuropsychological theory, as opposed to a different level of behavioural (neurophysiological) analysis (Coltheart 2006; Shallice 2003).

Disorders of memory

Memory disorder is a symptom of the utmost importance in psychiatric practice, in that it is one of the most sensitive indicators of brain damage or dysfunction, regardless of underlying pathology.

Neurological amnesias can be transient or persistent. Moreover, the persistent forms can be divided into two broad categories: those resulting from focal and those arising from diffuse cerebral disorder. In the former, amnesic defects can result from lesions in highly discrete parts of the brain and stand out against the relative preservation of other cognitive functions. In the latter, amnesic defects form an integral part of more widespread cortical and subcortical disease, as in dementia, or part of acute or subacute cerebral dysfunction, as in delirium. Moreover, memory loss can result from psychogenic disturbance, where there may be brain dysfunction but brain damage is not causative. Therefore, after a general background introduction, memory disorder is considered below in terms of (i) transient amnesias, (ii) the brain systems mainly involved in memory disorders, (iii) the clinical picture and pattern of neuropsychological deficits in common amnesic states, (iv) confabulation, (v) amnesia in diffuse cerebral disease, and (vi) psychogenic and psychiatric forms of memory loss.

General background introduction

The relationship between disorder of memory and cerebral pathology has repaid detailed study, and clinicopathological correlations have here reached firmer ground than where many other psychological symptoms are concerned. This is largely because many aspects of memory are amenable to objective testing and because relatively discrete lesions give rise to memory deficits and these lesions can be mimicked in animal investigations. These are both features that are rarely

encountered in other psychiatric syndromes. However, many controversies remain.

Theories of memory exist at many levels. Physiological theories postulate changes in electrical activity of neurones and their interconnections; such theories serve to explain very short-term storage, but for the establishment of durable memories there must be the ability to withstand profound derangement of electrical activity as in anaesthesia, hypothermia or convulsions. Biochemical theories suggest changes in the synthesis of neurotransmitters and intracellular proteins, or changes in gene expression within the neurone, but fail to take account of how brain systems operate and interact. Connectionist theories follow Hebb (1949) in postulating anatomical changes in synaptic relationships between cells (e.g. Meeter & Murre 2004) but some of their postulates are not directly testable.

Squire (1987), Kandel and Hawkins (1992) and Tranel and Damasio (1995) have discussed findings in this area. Studies of the mollusc *Aplysia*, for example, have shown unequivocal evidence both of changes in transmitter release and morphological alterations in synapses during learning. The discovery that brief high-frequency stimulation can alter the excitability of postsynaptic cells in the hippocampus for several hours or even weeks (long-term potentiation, LTP) has also been shown to have relevance to learning. The initiation of LTP is subserved by the binding of glutamate to receptors on target cells, whereas its maintenance appears to depend on some factor, possibly nitric oxide, which acts in a retrograde manner on presynaptic terminals to enhance transmitter release. Both electrical and biochemical theories are brought together by the discovery that the *N*-methyl-D-aspartate (NMDA) glutamate receptor has a channel that opens to extracellular ions only when the cell is depolarised. This dual requirement for both receptor binding and electrical depolarisation suggests that NMDA receptors may act as conjunction detectors in the hippocampus with a role in associative learning. Nevertheless, the findings from biochemistry have been disappointing, both in terms of improving our understanding of human memory disorders and in terms of producing potent pharmacological agents for their treatment.

Two main regions of the brain that have emerged as especially significant in relation to anterograde amnesia are the diencephalon and the medial temporal lobes. They lie within circuitry that also encompasses the mamillary bodies, fornix and retrosplenium. Damage within this circuitry can selectively impair the capacity to form durable records of experience. It is associated also with a variable retrograde gap for memories laid down before the damage occurred (Rempel-Clower *et al.* 1996). It used to be thought that earlier memories remained substantially intact, and that these sites did not themselves represent the 'repositories' or storehouses of memories but were concerned with adding to the store and perhaps with retrieval from the store (Squire & Alvarez 1995).

However, a more recent view is that the hippocampus (perhaps together with other medial temporal structures) is indeed a component in the memory engram, acting as a pointer or index of memories for episodes, whatever their age (Nadel & Moscovitch 1997). According to this view, every time a memory is retrieved or reactivated a new trace is laid down, resulting in the accumulation of 'multiple traces'.

Besides these parts of the brain, other neural systems must be implicated in the processes of remembering. We preserve in memory mainly those things towards which attention is directed, and alerting and 'executive' mechanisms must therefore be involved. The emotional connotations of material can also influence memory recall (Lishman 1972, 1974; Master *et al.* 1983; Rubin & Schulkind 1997; Buchanan *et al.* 2005), and the amygdalae and frontal systems are implicated in this. Other variables affect the content of what is encoded and retrieved, such as interest and motivation, relevance, importance, and consistency with existing frames of reference (Bartlett 1932; Schacter 2001). Hence, memory provides fertile ground for the influence of psychosocial factors and, in extreme instances, for the occurrence of psychogenic impairment. In short, the clinicopathological correlations obtained in neurological amnesias may reveal only a part of the total mechanisms involved in remembering.

Transient amnesias

Transient amnesias can be particularly informative because they are dense and then, by definition, they recover.

Transient global amnesia (TGA) most commonly occurs in the middle-aged or elderly, more frequently in men. It encompasses a period of anterograde amnesia lasting several hours. It is characterised by repetitive questioning, and there may be some confusion, but unlike psychogenic forms of amnesia, patients do not report any loss of personal identity. It is sometimes preceded by a headache or nausea, a stressful life event, a medical procedure, intense emotion or vigorous exercise. Hodges and Ward (1989) found that the mean duration of amnesia was 4 hours and the maximum 12 hours. In 25% of their sample, there was a past history of migraine, which was considered likely to have had an aetiological role. In 7% of cases, the patient subsequently developed epilepsy, in the absence of any previous history of seizures. There was no association with a past history of, or risk factors for, vascular disorder or transient ischaemic attacks. In 60–70% of the sample, the aetiology was unknown. Similar findings were obtained by Miller *et al.* (1987) in a sample of 150 men and 127 women. Again, the incidence of cerebral vascular events was no higher than would be expected in this age group.

Neuropsychological testing during the episode confirms a profound anterograde amnesia on tests of both verbal and non-verbal memory, but retrograde amnesia is variable, usually being relatively brief but occasionally more exten-

sive. Although the clinical impression is of complete recovery following the attack, both Miller *et al.* (1987) and Hodges and Oxbury (1990) found evidence of subtle but statistically significant residual impairments on some neuropsychological tests. There is now evidence from a number of sources that medial temporal lobe, vasospasm, hypoperfusion, and spreading depression within white matter is the underlying basis of TGA. Evidence supporting this hypothesis comes from investigations using single-photon emission computed tomography (SPECT), positron emission tomography (PET) and diffusion-weighted MRI.

Transient epileptic amnesia (TEA) is a term coined by Kapur (1990). It refers to that subgroup of TGA cases in which epilepsy appears to be the underlying cause. The main differences from other cases of TGA are that where seizure activity underlies the dysfunction, the episodes of memory loss are brief (1 hour or less), and that patients are more likely to experience multiple attacks (Hodges & Warlow 1990). It is important to note that standard electroencephalography (EEG) and CT or MRI findings are often normal; however, an epileptic basis to the disorder may be revealed on sleep-deprived EEG. Although 'transient epileptic amnesia' is a useful term, there may be variants within it, notably between cases in which the amnesic episodes are ictal and those in which they are postictal in nature. As will be mentioned below, it appears that many patients who report TEA attacks also describe 'gaps' in their past autobiographical memory. There is controversy about the nature of these autobiographical memory gaps, but the most parsimonious explanation would be that there have been clinically undetected brief runs of seizure activity in the past, which resulted in faulty (anterograde) encoding of very specific items in autobiographical memory. Hence the patients complain of 'gaps' in autobiographical memory rather than more global impairment.

Brain systems involved in memory disorder

Diencephalic amnesia

Lesions in the posterior hypothalamus and nearby midline structures were the first to be firmly linked with amnesia. They constitute the principal pathological basis of Korsakoff's syndrome, and involve areas around the third ventricle, the periaqueductal grey matter, the upper brainstem, certain thalamic nuclei and the posterior hypothalamus. The mamillary bodies along with the terminal portions of the fornices are nearly always affected, and publications reviewed by Brierley (1966) suggested that damage confined almost exclusively to the mamillary bodies can account for the Korsakoff memory defect. However, in a detailed neuropathological study Victor *et al.* (1971) argued that lesions in the medial dorsal nuclei of the thalamus were of more critical importance, and may in fact be crucial for the development of amnesic symptoms in Korsakoff's syndrome.

Debate has continued over the relative importance of the mamillary bodies and the thalamic nuclei in Korsakoff patients, or indeed whether both must be involved together (Mair *et al.* 1979). Kopelman (1995) has reviewed evidence suggesting that a circuit involving the mamillary bodies, the mamillothalamic tracts and the *anterior* (rather than the medial dorsal) nuclei of the thalamus may be particularly critical for memory formation. Investigations by Mayes *et al.* (1988) and Harding *et al.* (2000) have supported the importance of this circuitry, and of lesions to the anterior rather than medial dorsal thalamic nuclei.

The common cause for lesions in this situation is thiamine deficiency, the amnesic difficulties developing as a sequel to Wernicke's encephalopathy (Chapter 11, Wernicke's encephalopathy). Chronic alcoholism is nowadays by far the commonest cause of a Wernicke episode, but other established causes include carcinoma of the stomach, pregnancy, severe malnutrition, or persistent vomiting from any cause.

The term 'Korsakoff's syndrome' is probably best reserved for such cases where thiamine depletion is the underlying aetiology, and 'amnesic syndrome' can be used more generally to describe those disorders which follow other forms of damage to the same brain regions. Tumours in the neighbourhood of the hypothalamus and third ventricle may produce a closely similar picture (Guinan *et al.* 1998). Sub-arachnoid haemorrhage may occasionally be followed by a pronounced amnesic syndrome due to local haemorrhage or organisation of the clot in the basal regions of the brain. In the severe stages of tuberculous meningitis, a picture closely similar to Korsakoff's syndrome may be witnessed over many weeks; following recovery normal memory function gradually returns, leaving only an amnesic gap for the acute phase of the illness and a retrograde amnesia for a variable period before it (Williams & Smith 1954). The characteristic pathology of tuberculous meningitis in the amnesic phase is an inflammatory process with organisation of exudate, largely limited to the anterior basal cisterns of the brain and involving the mamillary region and the floor of the third ventricle. There is evidence to suggest that these regions have escaped the main impact of the infective process in those few cases where memory difficulties do not appear.

While the importance of diencephalic and hypothalamic lesions in relation to amnesia cannot be doubted, it is important to remember that the pathology of Korsakoff's syndrome involves additional brain regions, and that these may include structures which contain important neurochemical nuclei. There is usually concomitant frontal lobe atrophy, which may give rise to behavioural features such as apathy, and, when severe, can be the basis of confabulation (Kopelman 2002). Adrenergic, serotonergic and cholinergic depletions have all been reported in Korsakoff's syndrome with accompanying claims of aetiological importance. None of these has produced any major therapeutic advance to date,

although this may be partly because there has been a dearth of adequate therapeutic trials in this disorder.

Medial temporal amnesia

Long after the description of Korsakoff's syndrome, an amnesic syndrome was described that was closely similar in phenomenology to that of the Korsakovian defect. This was first fully recognised after surgical extirpation of brain tissue for the relief of psychotic disorders and epilepsy (Scoville 1954; Scoville & Milner 1957). It results from bilateral lesions of the hippocampus and hippocampal gyrus, with variable involvement of structures within the parahippocampal gyri including the entorhinal, perirhinal and parahippocampal cortices (Corkin *et al.* 1997). In the surgical cases, the extent of their resection appeared to be roughly proportional to the severity of the memory disorder (Milner 1966), and bilateral lesions were required before a severe and global amnesia appeared. When amnesic symptoms have followed unilateral temporal lobe resection there has usually been evidence that the remaining hippocampal zone was also dysfunctional (Warrington & Duchon 1992). Unilateral resections generally give rise to a material-specific, more moderate memory impairment. Serafetinides and Falconer (1962) found that mild subjective forgetfulness sometimes followed unilateral right lobectomy, but in all such cases there was also evidence of a postoperative spike-discharging focus at the opposite temporal lobe, indicating dysfunction if not a lesion there.

Other aetiologies can also give rise to medial temporal amnesia. Cerebrovascular accidents may sometimes be followed by the acute onset of amnesic difficulties, as in the patient described by Victor *et al.* (1961) who suffered occlusion of each posterior cerebral artery in turn, and at autopsy was found to have lesions in the inferomedial portions of each temporal lobe. Two years intervened between the two strokes and it was only after the second episode that the amnesic syndrome appeared. The severe memory impairments that follow herpes encephalitis also result from pathology in this distribution, since the herpes simplex virus has a predilection for the medial temporal lobe structures including the hippocampi (Brierley *et al.* 1960; Cermak & O'Connor 1983; Wilson *et al.* 1995; Stefanacci *et al.* 2000). Evidence from epilepsy similarly points to the importance of the hippocampal areas for memory, since these are the regions implicated in complex partial seizures where amnesia constitutes an essential feature of the attacks, and interictal memory complaints are common. Cerebral hypoxia or hypoxia/ischaemia is another cause of hippocampal amnesia as in the patient reported by Zola-Morgan *et al.* (1986) who developed a marked and persistent anterograde amnesia after ischaemic damage restricted to the CA1 fields of the hippocampi bilaterally.

High-resolution MRI has proved capable of visualising hippocampal damage during life in amnesic patients. Press *et al.* (1989) reported three patients with circumscribed

amnesic states, one due to respiratory arrest and the others of unknown aetiology, all of whom showed bilateral hippocampal abnormalities on coronal T1-weighted images taken perpendicularly to the long axis of the hippocampus. Quantified measurements of the hippocampi on three-dimensional MRI have now been carried out in many investigations of amnesia and dementia (Chan *et al.* 2001; Colchester *et al.* 2001), and good correlations with measures of anterograde memory can be obtained (Kopelman *et al.* 2001).

Other brain structures implicated in memory processes

Early reports suggested that the fornix bundles, which provide the main connection between the hippocampi and the hypothalamic structures, could be cut bilaterally without disturbing memory (Dott 1938; Cairns & Mosberg 1951). Such patients, however, were not subjected to formal neuropsychological evaluation. More recently, memory deficits have been documented after lesions of the fornix, even in the absence of CT or MRI evidence of damage to other key memory structures (Grafman *et al.* 1985; Hodges & Carpenter 1991). The patient reported by Tucker *et al.* (1988) was particularly interesting in that a small focal astrocytoma of the left fornix led to a memory deficit confined to verbal material, much as would be expected from a left hippocampal lesion. Aggleton *et al.* (2000) reported memory disorder, particularly affecting recall memory, in a series of patients with choroid cysts implicating the fornix.

Disruption of the memory circuitry and resulting memory disorder also occurs in retrosplenial lesions arising from vascular accidents or with tumours of the splenium of the corpus callosum (Valenstein *et al.* 1987; Rudge & Warrington 1991). The retrosplenial cortex is situated in the cingulate gyrus just above and posterior to the splenium, and contains relays between the anterior nucleus of the thalamus and the medial temporal lobe. Retrosplenial hypometabolism is commonly found in amnesic disorders in fluorodeoxyglucose (FDG)-PET investigations, whatever the underlying aetiology (Reed *et al.* 1999, 2003, 2005; Nestor *et al.* 2003).

The role of the frontal lobes in memory has been increasingly highlighted, especially since the advent of functional neuroimaging. Operations on the frontal lobes rarely produce persistently severe memory disorders, though in the early postoperative period there may be a striking deficit of retention of current experience together with patchy retrograde amnesia (Klein 1952; Kral & Durost 1953). Whitty and Lewin (1960) described a transient memory disorder involving especially the temporal sequence of events following limited ablations of the anterior cingulate cortex. The early amnesic patient recorded by Mabilie and Pitres (1913) was found to have symmetrical areas of infarction in the frontal white matter, strategically placed to interrupt long association fibres from the frontal lobes to other parts of the brain. More recently, Wheeler *et al.* (1995) reviewed the evidence on frontal lesions and memory, finding impairments in both

recall and recognition memory in the vast majority of studies.

It remains a matter of controversy whether the frontal lobes play a primary role in memory *per se* or merely influence memory processes by virtue of their involvement in attention and other executive functions. There are numerous pathways between the prefrontal cortex and the medial temporal lobe structures, and their interaction is a current topic of active research. It is now well established that there is frontal involvement in relation to special aspects of memory processes, for example in the suppression of irrelevant associations, in memory for temporal order and spatiotemporal context (source memory), and in the efficient retrieval of memories from the past (Mayes *et al.* 1985; Schacter 1987; Mayes 1988; Kopelman 1991). The role of superadded frontal lobe damage in Korsakoff's syndrome has been especially closely studied (see Chapter 11). There is hemispheric and subcortical (basal ganglia) specialisation for experience as displayed in verbal, visuospatial or motor learning. A temporal lobe (hippocampal) lesion in the hemisphere dominant for speech impairs the learning and retention of verbal material, resulting for example in forgetfulness for names, material read in newspapers or material heard in lectures. Conversely, patients with non-dominant temporal lobe lesions are impaired in memorising that which cannot be categorised in words, such as tunes, faces and meaningless drawings. There is now a considerable body of experimental data available on such distinctions between left and right hemisphere lesions.

There is now a vast literature on functional brain activation techniques (PET, fMRI) in memory, which it is beyond the scope of this chapter to review. However, early investigations suggested that the left frontal region was particularly involved in the encoding of episodic memories, whereas the right frontal region, together with the precuneus, was of particular importance in episodic memory retrieval (Shallice *et al.* 1994; Tulving *et al.* 1994; Fletcher *et al.* 1995). In contrast, other investigations have produced evidence of more traditional left-right material-specific asymmetries during memory encoding in both the medial temporal lobes and the prefrontal cortex (Golby *et al.* 2001). Many investigations have reported activations in the hippocampi and medial temporal lobe structures. Lepage *et al.* (1998) argued, on the basis of a matter-analysis, that anterior medial temporal activations were associated with memory encoding and posterior activations with retrieval, whereas Schacter and Wagner (1999) found that encoding activations were associated with both anterior and posterior activations. Some studies have examined the relationship between frontal and hippocampal activation in consolidation (Kopelman *et al.* 1997), whereas others have reported differential patterns of hippocampal and parahippocampal activation during more recollective or familiarity-based memory processes (Davachi *et al.* 2003; Ranganath *et al.* 2004).

There are also functional imaging studies that have examined the retrieval of more remote, episodic memories. Some investigations have reported greater hippocampal activation in the retrieval of recent, as opposed to remote, episodic memories (Haist *et al.* 2001; Mayes *et al.* 2004a), whereas other studies have found that medial temporal lobe structures (the hippocampi in particular) are significantly activated in retrieving both recent and remote autobiographical memories (Ryan *et al.* 2001; Maguire *et al.* 2001). More recently, Gilboa *et al.* (2004) reported that the pattern of activations within the hippocampi may vary between remote and recent memory retrieval, the latter tending to show more anteriorly positioned hippocampal activations.

Clinical picture and pattern of neuropsychological deficits in amnesia

Definitions

The clinical and neuropsychological pattern of deficits seen in amnesic states has been extensively studied in patients who are relatively free from other intellectual impairments, usually in patients with focal lesions in the diencephalon or medial temporal lobes. In clinical practice, there is often some degree of concomitant cortical atrophy and/or confounding psychological problems such as depression or post-traumatic stress disorder.

For purposes of clinical description, a somewhat arbitrary division can be made into immediate, recent and remote memory. The *immediate memory span* is reflected in the reproduction of material such as brief digit sequences which fall within the span of attention. This memory span appears to represent the functioning of short-term memory mechanisms, which need not, even in normal circumstances, lead to an enduring record. (Clinically, this is often interpreted as evidence that 'registration' is intact.) *Recent memory* is reflected in the ability to acquire and retain new knowledge (termed 'current memorising' or 'new learning') and is assumed to require a process of consolidation in addition to initial encoding or registration. Clinically, it is assessed by testing the ability to recall simple information (exceeding the memory span) after at least a minute has elapsed. *Remote memory* is reflected in the ability to recall events or facts acquired at a considerable distance in time, and certainly before the onset of the memory difficulties, i.e. an impairment in remote memory indicates retrograde amnesia.

In everyday clinical practice, it is convenient to employ the terms 'immediate', 'recent' and 'remote' as outlined above. Unfortunately, however, considerable confusion has arisen over some of the terms commonly used in referring to memory mechanisms. For example, 'short-term memory' is used by experimental psychologists as synonymous with the immediate memory span, whereas in medical practice it is usually taken as congruent with recent memory. The term

is best avoided or, if used, employed in a strictly experimentally defined (research) sense.

An important division is recognised between primary and secondary memory mechanisms both in animal and human experimental work. Each has certain characteristics not shared by the other. Primary memory has a strictly limited capacity, being able to hold only a small number of unrelated items of information at a time. Decay from it is rapid when rehearsal is prevented. This is the aspect of memory tested by the digit span. The material held in primary memory is retained in a form closely tied to the qualities of the initial percepts (timbre, visual detail, precise verbal content, etc.); it is largely non-selective, and material can be reproduced from it with minimal comprehension of the meaning. Subsequent entries to the system displace what is already there. Primary memory thus acts as a short-term back-up to perceptual experience, giving time for selective attention to focus on what is meaningful and valuable for processing into secondary memory.

Working memory (Baddeley 1976; Hitch 1984) is an elaboration of the concept of primary memory described above. It emphasises those components that can hold information in short-term storage and manipulate it while performing ongoing cognitive tasks, and it recognises the existence of different subsystems dealing with specialised forms of material. The 'articulatory loop', for example, deals with phonological information, the 'visuospatial scratch pad' with visual images. Suitable experimental paradigms, and studies in patients with brain lesions, can show the relative independence of the one from the other (Vallar & Papagno 1995).

Secondary memory has very different properties. Material held in secondary memory is encoded more commonly in semantic terms, i.e. in the form of meaningful schema or concepts, and the primary qualities of the percepts may become somewhat obscured. The result is a far more durable record. There is no known limit to the amount that can be stored. Secondary memory (also known as 'long-term memory' in experimental psychology) thus encompasses all material retained beyond a period of several seconds, and includes both recent and remote memories.

Studies carried out in both normal subjects and patients with amnesia have generally upheld these broad divisions, though complex interrelationships clearly exist between these memory storage systems. Valuable reviews of experimental work are to be found in Squire (1987) and Parkin (1987).

The *episodic-semantic* distinction was introduced by Tulving (1972) and relates to events and facts held within secondary memory. Episodic memory refers to memory for specific, personally experienced events or episodes from the individual's past and to the ability to travel back mentally in time. Semantic memory deals essentially with organised knowledge about the world which does not have a specific location in time or place – knowledge of objects, labels,

vocabulary, principles and concepts. As such, it is a shared form of knowledge, much of which is acquired early in life. Both the episodic and semantic aspects of memory can be affected (or spared) in memory disorders. Hence, episodic memory is particularly (although not usually exclusively) affected in the amnesic syndrome, whereas semantic memory is particularly damaged in semantic dementia, involving focal temporal lobe atrophy.

A further distinction is made between *explicit* or *declarative* and *implicit* or *procedural* memory. Explicit or declarative memory refers to conscious awareness of past events or facts (Squire 1987). It embraces both episodic and semantic memory as defined above. Implicit memory refers to the facilitation of particular responses or to perceptuomotor skill acquisition and retention, which does not require (and may be inhibited by) conscious awareness of the learning episode. This 'knowing how' to do it is expressed in performance, not in conscious recollection. The phenomenon of 'priming' involves the facilitation of responses to cues such as previously perceived, partially completed or semantically related words. The various forms of procedural memory include motor skills (e.g. how to ride a bicycle or tie shoe laces) and the capacity to perform certain cognitive operations (e.g. how to solve certain types of puzzle). Implicit memory is characteristically preserved when explicit memory is severely disrupted in the amnesic syndrome.

Thus there appear to be several independent memory systems, and these are related to different neural networks within the brain. Explicit episodic memory is damaged by medial temporal and diencephalic lesions. There is some evidence that impairments in skill learning may be related to damage in the striatum, and priming effects to neocortical pathology (Squire 1986; Kopelman 2002). Semantic memory is particularly affected by atrophy or pathology in the inferior and lateral temporal lobes, more commonly on the left.

Clinical picture

In the amnesic syndrome, perception is unimpaired, the immediate memory span is well preserved, and there is severe impairment of new learning (anterograde amnesia) and a variable retrograde amnesia usually with a so-called 'temporal gradient', i.e. relative sparing of early memories.

Preservation of the immediate memory span is a point of importance clinically. Performance on a test of digit span is usually normal, and therefore will fail to reveal the existence even of a severe amnesic syndrome. Patients with bilateral temporal lobe resection, in whom good ability to cooperate is well preserved, have shown that in the absence of distraction such brief information can be retained for as long as several minutes by dint of constant verbal rehearsal. However, forgetting occurs as soon as new activity demands a shift away from the task in hand. Moreover, the learning of a list which only slightly exceeds the normal digit span is markedly impaired, revealing the essential difficulty in

getting new material into longer term store (Drachman & Arbib 1966).

Current and recent memory (i.e. new learning) is severely impaired, and disorientation in time is almost universal. In the most extreme cases, new learning may be reduced to virtually nil, so that as time goes by there is a continuing and extending anterograde amnesia. If recovery subsequently occurs (e.g. following head injury), a dense and permanent gap will be left for the period of the illness. In less severe examples the problem shows as uncertainty about events that occurred minutes, days or weeks before, some being vaguely recalled and others having made no lasting impression at all. The retelling of simple stories is marked by gross omissions, incorrect juxtapositions and condensations of material. Testing reveals that the problem affects all types of material, both verbal and non-verbal, such as word associations, drawings and numbers.

It seems clear also that these defects of memory are to a large extent independent of the significance of the material involved. Events of high emotional significance may sometimes appear to be remembered especially well (Hamman *et al.* 1997) but this is not always the case. Milner (1966) reported of H.M.:

His initial emotional reaction may be intense, but it will be short-lived, since the incident provoking it will soon be forgotten. Thus, when informed of the death of his uncle, of whom he was very fond, he became extremely upset, but then appeared to forget the whole matter and from time to time thereafter would ask when his uncle was coming to visit them; each time, on hearing anew of his uncle's death, he would show the same intense dismay, with no sign of habituation.

Victor (1964), in a group of alcoholic Korsakoff patients, was unable to discern any factors that governed what was remembered and what was forgotten. A patient might fail to retain news of a bereavement which shocked him profoundly at the time, yet retain other matters of no significance whatever. More recently, evidence has been reported that a number of severe amnesic patients show very slow acquisition of semantic memories, possibly by cortical mechanisms, in the absence of discernible episodic memory acquisition (McCarthy *et al.* 2005).

Despite such pervasive deficits, procedural memory is well preserved, even in the most severely affected patients. Milner's (1966) patient, for example, showed a normal learning curve for a task of mirror drawing, even though on each test occasion he was completely unaware that he had tried the task before. Other motor and perceptual skills, such as on pursuit-rotor tasks or (more importantly) musical skills, are well preserved even if the patients lack awareness of still having these skills (Corkin 1968; Starr & Phillips 1970; Wilson *et al.* 2008). 'Priming effects' are largely preserved, as when prior presentation of a word increases the tendency to produce that word when its initial letters are shown some

minutes later (Squire *et al.* 1987). Thus the forms of memory that are accessible only in performance, and not as acts of conscious recollection or recognition, appear to be spared in the classic amnesic syndrome.

The retrograde amnesia often covers a period of months, years or even decades before the onset of the illness. This is usually dense for events just prior to the onset, but may be incomplete, patchy and lacking in detail for the earliest memories. Time sense is characteristically disordered within the retrograde gap, with jumbling of the sequential ordering of those events which are recalled. In patients with Korsakoff's syndrome of alcoholic origin, the retrograde amnesia characteristically extends back 20–25 years, sometimes longer, and shows a clear-cut temporal gradient (Kopelman 1989). In discrete amnesic syndromes of other aetiologies the retrograde amnesia is very variable according to case reports and experimental investigations. Some studies report a short retrograde loss of 2–4 years in hippocampal lesions (Reed & Squire 1998; Kapur & Brooks 1999), others a much more extensive retrograde loss (Viskontas *et al.* 2000; Cipolotti *et al.* 2001).

According to Ribot's (1882) 'law', early memories are always relatively preserved, but there is now considerable controversy about whether this always occurs or whether it reflects a clinical impression based on oft-repeated stories. The issue relates to the various theories which purport to explain the occurrence of retrograde amnesia (see below).

Disturbance of time sense and of the ordering of events is an outstanding characteristic, particularly in Korsakoff's syndrome. The patient may allocate some recent remembered event to the distant past, or (much more commonly) bring up a past event as a recent happening. He may condense long periods of time or telescope repeated happenings into one (Korsakoff 1889; Victor *et al.* 1971). This affects recent memory and the period of the retrograde gap particularly, but may be observed for more remote happenings as well. Talland (1965) suggested that the problem is due not to a loss of appreciation of the flow of time, but rather to 'contextual isolation'; that is to say, events within the memory store appear to lose relationship with the totality of experience which surrounds them, sometimes referred to as a loss of 'temporal tagging'.

Other cognitive functions are relatively well preserved, and the above amnesic deficits are out of all proportion to other disturbances of intellect or behaviour (Victor *et al.* 1971). In particular the patients are alert, responsive to their environments and without any evidence of clouding of consciousness. However, where pathology is more widespread, as can occur in Korsakoff's syndrome, cerebral hypoxia, vascular pathology or herpes encephalitis, the situation is less straightforward. Other cognitive functions may be disordered when carefully examined (Talland 1965; Zangwill 1966; Victor *et al.* 1971). Where there is concomitant frontal lobe involvement, there is often difficulty in sustaining

mental activity, coupled with inflexibility of set and reduced capacity to shift attention from one task or train of thought to another. Thinking is usually stereotyped, perseverative and facile, with inadequate concept formation and defective ability to categorise. Butters and Cermak (1980) found visuo-perceptual impairments in Korsakoff patients when sought by special tests, for example the digit-symbol substitution test, hidden figures test, or tests requiring the sorting and discrimination of complex visual stimuli. However, all these impairments are nonetheless overshadowed by the prominence of the memory disorder. It is this disproportion between severe memory deficits and other (subtle) cognitive deficits that defines the amnesic syndrome. However, there are undoubtedly transitional forms between the classic picture and patients with variable degrees of more global cognitive impairment.

In Korsakoff's syndrome, and some other amnesic patients (e.g. following herpes encephalitis), there may be certain marked disturbances of personality. There is often a pronounced degree of apathy and loss of initiative, a bland or even fatuous disposition, and a tendency towards self-neglect. Left alone, the patient occupies himself poorly, makes few demands or enquiries from those around, and obeys instructions in a passive and indifferent manner. A virtual disinterest in alcohol may represent a particularly striking change. Lack of insight is also almost universal; few severely amnesic patients are overtly aware of their deficits, and in those who do the gravity of these defects is minimised or explained away by facile rationalisations.

The neuropsychological deficit

The amnesic syndrome was for many years regarded as reflecting a failure of consolidation of new experience. Thus while the immediate memory span is normal, and early memories may remain substantially intact, current experience cannot gain proper access to the secondary memory (Milner 1966). However, a simple consolidation hypothesis is hard pressed to explain why some forms of cueing can improve performance, or why patients can achieve better results on recognition tests than when tested by free recall. Moreover, if consolidation were the explanation of an extensive retrograde amnesia, where it occurs, this would imply that the process of physiological consolidation lasts for years, even decades.

Butters and colleagues stressed the role of deficient semantic encoding of information in leading to the poor performance of amnesic subjects (Butters & Cermak 1980). This, it was argued, might account in considerable degree for their failure to store material adequately. Thus, patients with Korsakoff's syndrome were found to rely unduly on simple acoustic encoding of the information they receive, rather than analysing it more deeply in terms of semantic meaning. Moreover, they use inappropriate strategies for the rehearsal and 'chunking' of information, all rendering information more susceptible to interference and rapid decay. When spe-

cifically instructed to attend to the semantic features of presented stimuli, for example in terms of categories, attributes or meaning, patients with Korsakoff's syndrome are found to achieve a somewhat improved performance on memory tasks, although considerable impairment remains (Meudell *et al.* 1979; McDowell 1981).

Another theory is that there is a specific deficit in the amnesic patient's acquisition of contextual (e.g. temporal and spatial) information, resulting in disproportionate impairments in contextual memory (Huppert & Piercy 1976, 1978a; Mayes *et al.* 1985). More recently, this theory has evolved into a more generalised notion of a deficit in binding complex associations (Mayes & Downes 1997) or in binding the relations between items (Cohen *et al.* 1997). This specific deficit in combining complex associations or relations between items is usually attributed to hippocampal pathology, or dysfunction, and results in various related distinctions being postulated in amnesia, including those between recollection and familiarity memory, recall and recognition memory, remembering and knowing, as well as that between 'explicit' and 'implicit' memory.

Another possibility is that there is a specific deficit in 'storage' (retention) rather than in learning processes, at least in some amnesic patients. It was found that, after learning has been acquired, many amnesic patients show a normal rate of forgetting, at least on recognition memory tests (Huppert & Piercy 1978b; Kopelman & Stanhope 1997), but there is some evidence that patients with medial temporal lobe pathology might forget at an accelerated rate, even after learning has been acquired (Huppert & Piercy 1979; Parkin & Leng 1988). However, various studies have failed to demonstrate this (Kopelman 1985a; McKee & Squire 1992), although there is some evidence that, over and above their initial acquisition or learning deficit, amnesic patients show accelerated forgetting when tested on recall (as opposed to recognition) memory tasks over a period of minutes (Kopelman & Stanhope 1997; Green & Kopelman 2002).

A further possibility is that the deficit occurs at retrieval. Warrington and Weiskrantz (1968) postulated that amnesic patients were unable to suppress inappropriate responses during recall and recognition memory tasks. They noted that such patients sometimes respond erroneously with what had been the correct responses to previous test items, and that the provision of retrieval cues can improve their performance. On the other hand, it was later found that healthy subjects exhibited these phenomena when given memory tests at relatively long delay intervals, suggesting that they were a consequence of poor memory rather than its cause (Mayes & Meudell 1981). Subsequently, Warrington and Weiskrantz (1982) retracted this view, arguing instead that lesions in diencephalic or medial temporal structures might 'disconnect' a critical memory circuit running between frontal cortex, subserving 'cognitive mediation', and a semantic memory system in the temporal lobes.

Amnesic syndrome or syndromes

In the past, there was an extensive debate concerning whether there was a differential pattern of amnesic deficit in comparing patients with diencephalic and those with medial temporal lobe pathologies. On the one hand, Warrington and Weiskrantz (1982) argued that these structures were all part of the same memory circuitry, damage in which 'disconnected' a frontal cognitive mediation system from a temporal lobe semantic or conceptual memory system. In contrast, others argued for differential patterns of memory deficits on the basis of findings with respect to measures of forgetting rates or contextual (temporal and spatial) memory (Huppert & Piercy 1979; Parkin 1987). In general, although there may be subtle differences in contextual memory, these differential patterns have not been corroborated (Kopelman 2002). Moreover, although a broad distinction between executive processes and encoding/retrieval mechanisms remains valid, there is also considerable overlap with the effects of large (particularly bilateral) frontal lesions, and a review of the latter showed that virtually all studies have reported impairments in recall (and often recognition) memory (Wheeler *et al.* 1995).

More recently, differences have been sought between the effects of damage to hippocampal and parahippocampal (particularly perirhinal) structures. Aggleton and Shaw (1996) argued that patients with pathology confined to the hippocampus showed impairments on verbal and visual recall but not recognition memory, whereas damage to parahippocampal structures was required to produce an impairment in familiarity-based or recognition memory. There were problems with the meta-analysis on which this hypothesis was based, but supportive evidence has been obtained in a number of investigations, notably by Holdstock *et al.* (2002) and Mayes *et al.* (2004b). On the other hand, others have argued that when appropriate experimental controls are introduced, patients with pathology confined to the hippocampus (as well as other amnesic patients) showed proportionate impairments on both recall and recognition memory procedures (Reed & Squire 1997; Manns *et al.* 2003; Kopelman *et al.* 2005). This issue remains hotly debated.

Lengthy retrograde amnesia

The short retrograde amnesia of several minutes' duration, such as commonly occurs after head injury, can plausibly be explained on the view that new learning requires a period of consolidation for stable long-term memory to be established. It is difficult, in contrast, to provide an explanation for the very long retrograde amnesias that may extend for years or decades before the onset of an amnesic syndrome. A number of authors have previously made this distinction between the different characteristics of short- and long-term retrograde amnesia (Symonds 1966; Kapur 1999). These lengthy retrograde amnesias are often patchy, and the patient may show a so-called 'temporal gradient', i.e. relative sparing of

early memories. Moreover, this lengthy retrograde amnesia may shrink with time (e.g. in head injury or tuberculous meningitis) but it can persist (e.g. in herpes encephalitis or Alzheimer dementia).

Neuropsychological studies have attempted to map the pattern of retrograde amnesia in amnesic disorders of various aetiologies. In a pioneering study, Sanders and Warrington (1971) employed a test requiring the recall and recognition of famous faces and a standardised questionnaire about public events from different time periods, finding a retrograde amnesia extending back many decades in a small group of amnesic patients. There was no evidence of a temporal gradient or sparing of early memories. In contrast, Albert *et al.* (1979, 1981), using closely similar tests, found striking evidence of a temporal gradient in patients with Korsakoff's syndrome, but not in patients with Huntington's dementia.

Subsequently, measures of personal or autobiographical memory were introduced (Zola-Morgan *et al.* 1983; Kopelman *et al.* 1989), and the debate has continued. For example, some authors have reported striking temporal gradients in amnesic patients (Kopelman 1989; Squire & Haist 1989; Kapur & Brooks 1999), whereas others have found 'flat' gradients in autobiographical memory and in the recall of public information, consistent with the original Sanders and Warrington finding (Viskontas *et al.* 2000; Cipolotti *et al.* 2001). Differential patterns across distinct diagnostic groups have been reported and, in general, there is a more 'gentle' temporal gradient in dementia patients, i.e. a lesser degree of sparing of early memories (Kopelman 1989; Kopelman *et al.* 1999).

Interesting hemispheric differences have been reported in memory-disordered patients. For example, De Renzi *et al.* (1987) reported a patient who was severely impaired after herpes encephalitis on a wide range of general or semantic information, but who appeared intact in retrieving autobiographical memories. This patient had extensive left temporal lobe damage. In contrast, others have reported disproportionate impairments in autobiographical memory with relative sparing of semantic knowledge in patients with predominantly right temporal lobe damage (O'Connor *et al.* 1992; Ogden 1993; Kopelman *et al.* 1999). This latter pattern has usually been attributed to the problems in retrieving the visual imagery associated with autobiographical memories.

These observations have implications for the interpretation of a lengthy retrograde amnesia. *Consolidation theory* assumes that a time-dependent physiological process is required to 'fix' memories in the brain, and to make them less vulnerable to the effects of brain pathology. This process has commonly been interpreted in terms of 'structural reallocation', which postulates that memories are initially dependent on (or stored in) medial temporal (or diencephalic) structures, particularly the hippocampi, but are later stored in the neocortex and are no longer dependent on the medial temporal/diencephalic system (Squire & Alvarez 1995;

Meeter & Murre 2004). This view predicts a temporal gradient in retrograde amnesia, as obtained in various studies cited above (Zola-Morgan *et al.* 1986; Kapur & Brooks 1999; Bayley *et al.* 2005). It is also supported by some fMRI investigations of remote memory, but is refuted by others. However, the theory cannot explain patients whose retrograde amnesia failed to show an unequivocal or any temporal gradient (Viskontas *et al.* 2000; Cipolotti *et al.* 2001). Moreover, a very extensive temporal gradient going back 20–30 years would imply that physiological consolidation must continue for a remarkably long time (Nadel & Moscovitch 1997).

The *semanticisation hypothesis* argues that, as memories for episodes are rehearsed, they adopt a more semantic form, losing their contextual immediacy or vividness, but protecting them from the effect of brain damage (Cermak 1984). In other words, the contextual components of these memories become attenuated or lost, making the memories feel much less immediate and vivid, but they are better preserved and protected against any subsequent retrieval deficit. One possibility is that this process involves the transfer of memories from the hippocampal system to the neocortex, in which case this theory overlaps with consolidation theory in postulating structural reallocation. A second possibility is that both episodic and semantic memories are stored in the neocortex, but only episodic memories require the hippocampus for their retrieval. A major problem for this theory is the finding that memories which are semantic virtually from the outset, such as knowledge of the meaning of new words, can also show a temporal gradient (Verfaellie *et al.* 1995).

Multiple trace theory, as mentioned briefly above, postulates that the hippocampi are continuously involved in the storage and retrieval (reactivation) of autobiographical memories, and that every time the reactivation of a memory trace occurs a new trace is laid down, resulting in 'multiple traces' (Nadel & Moscovitch 1997). In this theory, the memory trace for a specific episode is represented by a combination of 'binding codes' in the hippocampi and by fragments of information in neocortical association areas. The theory predicts that the extent of retrograde amnesia and the slope of the temporal gradient for autobiographical memories will depend on the size of hippocampal lesions or atrophy, and that a complete hippocampal transection would result in a 'flat' gradient for autobiographical memories. However, factual information is postulated as being stored in the neocortex independently of the episode in which it was acquired, and a steeper gradient for semantic than episodic memories is also predicted. Some functional activation investigations have provided findings consistent with this theory (Maguire *et al.* 2001; Ryan *et al.* 2001). On the other hand, many amnesic patients do indeed show a steep temporal gradient, as reported above, and Kopelman *et al.* (2003) failed to find the predicted significant correlations between hippocampal volumes and the extent or severity of retrograde amnesia in patients with primarily medial temporal lobe pathology.

Furthermore, retrograde amnesia gradients across autobiographical and semantic remote memory do not always fit the predicted pattern.

An alternative view, little discussed to date, is that the relative sparing of early memories in neurological amnesia reflects differences in the way that such early memories were originally encoded, making them more likely to be retrieved by healthy volunteers at a later date and also protecting them from the effects of subsequent brain damage. Kopelman *et al.* (1989) postulated such a hypothesis on the basis of age differences in the slope of temporal gradients in memory-disordered patients, and some recent observations would be consistent with such a hypothesis (Rubin & Schulkind 1997; Buchanan *et al.* 2005).

Disproportionate retrograde amnesia

Highly contentious is the nature of disproportionate retrograde amnesia, sometimes known as 'focal' or even 'isolated' retrograde amnesia. Many such cases have been reported in the literature, but they differ considerably in the circumstances and features of their onset, underlying clinical diagnosis, findings on neuroimaging, and the postulated site or sites of pathology, as well as in the adequacy of the clinical descriptions given. For example, Kapur *et al.* (1992) described a 26-year-old woman who had fallen from a horse, sustaining left and right frontal contusions, evident on CT, with subsequent signal alteration in the left and right temporal poles on MRI. This patient was severely impaired across all the remote memory tests with which she was investigated, but showed normal performance or only moderate impairment at various anterograde memory tests. However, the interpretation of her deficit was confounded by her subsequent development of various hysterical symptoms in the context of depression (Kapur 2000).

The underlying nature of such cases has been debated elsewhere (Kopelman 2000; Kapur 2000). Many of the cases described as 'focal retrograde amnesia' in fact showed evidence of anterograde memory impairment, especially for visuospatial material. Other cases showed poor anterograde memory in more moderate or subtle form across a number of tests, particularly story recall, face recognition memory, and delayed recall, begging the question of whether their failure reflects, in some sense, task demands and task difficulties. Some of the most convincing cases in this literature initially showed a severe anterograde amnesia as well as a severe retrograde amnesia. By the time of their assessment, the retrograde amnesia remained profound, whereas the anterograde amnesia had become only moderate, mild or minimal; in such cases, the real issue concerns differential patterns of recovery, and the way in which physiological or psychological factors can contribute to this. A further group of patients reported in the literature are those with TEA (see above), who commonly report 'gaps' in their autobiographical memories. However, it is not clear whether this has resulted from brief

'subclinical' runs of seizure activity in the past compromising encoding over short periods, or from current ictal activity inhibiting retrieval processes, or even causing an acceleration in the forgetting of 'old' memories: each of these views has been advocated. Finally, psychogenic factors may make an important contribution to the presence of a residual, disproportionately severe retrograde amnesia, and the reversed temporal gradient in psychogenic amnesia is identical to that seen in many cases of 'focal retrograde amnesia'. Psychogenic mechanisms may be important in those cases which follow a mild concussion, but also in some cases where there has been more severe brain pathology.

Confabulation

Confabulation can be a striking feature in amnesias, but in its 'spontaneous' form (see below) probably reflects concomitant ventromedial frontal pathology (Kopelman 1987a 2002). In the past, it has often (erroneously) been thought of as pathognomonic of diencephalic amnesia, but the relationship between diencephalic amnesia and confabulation has been greatly overstressed. When present, confabulation is commoner in the acute (Wernicke) stages than in the chronic phases of Korsakoff's syndrome but it is usually absent (Victor *et al.* 1971). It can also occur in temporal lobe amnesia (Wilson *et al.* 1995), but again it probably reflects concomitant frontal pathology. In general, it may appear as an evanescent phenomenon, or in rare cases it may last for many years.

Typically, the patient gives a reasonably coherent but false account of some recent event or experience, either in relation to his own activities or in response to suggestion by the examiner. Berlyne (1972) defined confabulation as 'a falsification of memory occurring in clear consciousness in association with an organically derived amnesia'. He upheld Bonhoeffer's early distinction between two varieties. The common 'momentary type' is brief in content, has reference to the recent past and has to be provoked. The content can sometimes be traced to a true memory that has become displaced in time or context. Much rarer is the 'fantastic type' in which a sustained and grandiose theme is elaborated, usually describing far-fetched adventures and experiences which clearly could not have taken place at any time. This form tends to occur spontaneously even without a provoking stimulus, and the content is often related to wish fulfillment and the seeking of prestige. Kopelman (1987a) preferred a classification simply into 'provoked' and 'spontaneous' confabulation, and has shown that the former appears in the context of efforts at recall by amnesic or dementia patients, whereas it is the latter that reflects specific (ventromedial) frontal pathology. Schnider *et al.* (1996) have provided important empirical evidence which supports this distinction.

Kopelman (1987a) was able to demonstrate examples of 'provoked' confabulation in healthy subjects when asked to recall prose passages after a considerable interval of time;

these were similar in nature to those sometimes observed in Korsakoff and Alzheimer patients when tested shortly after exposure, consisting mainly of additions of inaccurate or irrelevant material or changes in the sense of the passage. This type can thus be regarded as a 'normal' response to a faulty memory.

The evidence linking spontaneous confabulation to the presence of frontal lobe dysfunction includes the finding by Stuss *et al.* (1978) of five patients in whom frontal deficits, superadded to their memory problems, appeared to account for their persistent and extraordinary confabulation. Kapur and Coughlan (1980) were able to chart the change from fantastic to momentary confabulations in a patient with left frontal damage following subarachnoid haemorrhage, and to show that this change was paralleled by improvement in performance on frontal lobe or executive tests. Moscovitch and Melo (1997) reported that ventromedial pathology seemed to be the common factor in their patients, but others have disputed its critical importance (Dalla Barba 1993, 2002).

Sometimes confabulation may represent the residue of abnormal and confused experiences, including misidentifications and misinterpretations that occurred in the delirium of the initial Wernicke's encephalopathy. Thus, it commonly sets in as clouding of consciousness is receding and persists thereafter while insight into the unreal nature of the delirious experiences is lacking. As in delusions, the content of confabulation may appear 'motivated' or meaningful (Conway & Tacchi 1996).

Recent theories of spontaneous confabulation fall into three main groups. The first group of theories emphasises faulty specification and verification of memory retrieval. For example, Burgess and Shallice (1996) postulated deficits in a descriptor process, an editor process and a mediator process, which make differential contributions to the clinical phenomena of confabulation. Moscovitch and Melo (1997) put forward a somewhat similar argument, identifying a number of putative deficits in cue-retrieval, strategic search or faulty monitoring, the last resulting in erroneous memories not being edited out or suppressed. Likewise, Schacter *et al.* (1998) argued that an insufficiently 'focused' retrieval description, or an impairment in post-retrieval monitoring and verification, would give rise to confabulation. Moreover, encoding impairments would make subjects more liable to confabulatory errors at retrieval.

The second group of theories emphasises so-called source memory deficits, either with respect to confusion about the temporal context or sequence of memories, or in distinguishing between real and imagined memories. The belief that many confabulations may, in fact, be 'real' memories jumbled up and recalled inappropriately out of temporal sequence has a long history going back to Korsakoff (1889). In an empirical test of this hypothesis, Schnider *et al.* (1996) found that a small group of spontaneous confabulators were differ-

entiated from other amnesic patients and healthy controls on the basis of errors at an 'implicit' temporal context memory test (see also below). In a variant of this hypothesis, Dalla Barba (1993) and Dalla Barba *et al.* (1999) have proposed that 'temporal consciousness' is intact but malfunctioning in confabulating patients, who are aware of a past, present and future (unlike amnesic patients) but, in making temporal judgements, they employ only the most stable elements from their long-term memory stores. Asked what they did yesterday or what they will do tomorrow, the patients reply with the well-established routines or habits of a lifetime, irrelevant to their present situation. Johnson *et al.* (1993) postulated a wider range of context, source or reality monitoring deficits, in which a confabulating patient is unable to distinguish 'real' from imagined experience. Schnider *et al.* (2001) have more recently interpreted their experimental findings in these terms, arguing that deficits in a filter mechanism within the ventromedial frontal cortex results in the confabulating patient being unable to distinguish real memories from irrelevant thoughts and information.

A third group of theories emphasises that multiple deficits may contribute to confabulation. For example, Shapiro *et al.* (1981) postulated that confabulation results from (i) impaired self-monitoring, (ii) a failure to inhibit memory errors and (iii) frequent perseverations, each of these deficits being related to a different aspect of frontal/executive function. Johnson *et al.* (1997) concluded that confabulation may reflect an interaction between (i) a vivid imagination, (ii) an inability to retrieve autobiographical memories systematically and (iii) impaired source monitoring. Kopelman *et al.* (1997) found that (i) many confabulations in episodic memory were associated with temporal context errors, (ii) confabulations particularly in semantic memory were associated with perseverative errors and (iii) other confabulations appear to be unchecked, instantaneous, ill-considered responses to immediate environmental and social cues.

Amnesia in diffuse cerebral disease

When associated with diffuse cerebral disorder, memory disorder is often subsumed among more widespread impairments of intellectual function, making precise analysis of the memory deficits more difficult. In delirium, the memory difficulties can be traced to the combination of an impairment of consciousness and to problems in attention and perception. In dementias, memory complaints are often the earliest manifestation, in part perhaps because memory difficulties tend to be more readily identified than other aspects of intellectual loss. However, studies of Alzheimer patients show that some patients initially manifest an amnesic picture, whereas other initially show a dysexecutive syndrome (Becker *et al.* 1992; Hodges *et al.* 2003). The general picture of the memory difficulties in acute and chronic neurological disorders has been discussed earlier in this chapter (see Clinical picture

and pattern of neuropsychological deficits in amnesia). Certain distinctive features are summarised here for comparison with the picture in focal amnesic states.

The memory deficits in diffuse brain disease, such as *Alzheimer's dementia*, are extensive, affecting both recent and remote events to an obvious degree. Only rarely is there a clear-cut disturbance of anterograde memory with only a brief retrograde gap. However, recent events may be the most obviously affected, in part because of a lack of interest and involvement in current experiences. Remote memories may appear to be relatively intact, but their recall is often in fact banal, stereotyped and lacking in detail. There are now a large number of investigations reporting only a very gentle temporal gradient (relative sparing of early memories) in Alzheimer patients (Sagar *et al.* 1988; Kopelman 1989; Greene *et al.* 1995). Performance may be variable from one occasion to another, and capricious in that some events are easily recalled while others, apparently equally trivial or unimportant, are not. Indeed, part of the difficulty may lie in a failure to sustain attention and concentration on the general task of memory retrieval.

Evidence such as this suggests that the memory disorder in Alzheimer's dementia reflects diffuse cortical pathology as well as the characteristic atrophy and histopathological changes in the medial temporal lobes. Thus, the pattern of deficits is more extensive than that seen in the amnesic syndrome, and can be attributed to reduced neuronal interconnections, disrupted associations, impaired retrieval processes, and damage to the memory stores themselves. The immediate memory span is impaired (Miller 1973; Kaszniak *et al.* 1979), unlike the situation in patients with circumscribed amnesic syndromes, and forgetting occurs more rapidly within primary or working memory (Corkin 1982; Kopelman 1985a). However, once material has been acquired in secondary memory, forgetting rates on recognition memory tasks are surprisingly normal, suggesting that the main problem is in memory formation (Corkin *et al.* 1984; Kopelman 1985a), although faster forgetting can be found on recall memory tasks (Christensen *et al.* 1998). Kopelman and Corn (1988) reviewed and presented evidence that depletion within the cholinergic system in dementia can account only partially for the memory disorder encountered in such patients.

Findings in implicit memory in Alzheimer's dementia have been conflicting, and are closely tied to the specific test paradigms employed. The general picture that emerges in Alzheimer's disease is of preserved motor skill learning, as on pursuit-rotor tasks (Eslinger & Damasio 1986) and mirror reading (Deweert *et al.* 1993). On priming tasks, the findings are variable, depending on the precise experimental design (Shimamura *et al.* 1987; Brandt *et al.* 1988; Downes *et al.* 1996).

In Alzheimer's disease, the earliest and most intense pathological change is often in the hippocampal regions and this is correlated with the severity of the memory deficits (Brier-

ley 1961; Corsellis 1970; Braak & Braak 1991). Conversely, in the *frontotemporal dementias*, the pathological process may initially spare the hippocampal regions, and here episodic memory problems are rarely an early manifestation.

Semantic dementia is a temporal lobe variant of frontotemporal dementia. Many of its features were described by Pick (1892), but the first neuropsychological description was by Warrington (1975) and the term was coined by Snowden *et al.* (1989) and further employed by Hodges *et al.* (1992). In this syndrome, there is severe impairment in semantic memory (especially involving naming, word-finding, and comprehension) with relatively preserved episodic memory (for events) in the context of intact visuospatial abilities, number skills, reasoning and problem-solving, with good orientation in time and place. It most commonly involves unilateral atrophy of the left temporal lobe or bilateral temporal lobe atrophy with relative sparing of medial temporal lobe structures, although MRI studies clearly show that severe atrophy of medial temporal structures also emerges. Cases of relatively isolated right temporal lobe atrophy have also been described (Evans *et al.* 1995). Remote memory for early autobiographical events may also appear affected (Snowden *et al.* 1996; Graham & Hodges 1997), but this is almost certainly a consequence of the patients' deficits in semantic memory interfering with autobiographical memory retrieval, rather than a deficit in autobiographical memory storage *per se* (Westmacott *et al.* 2001; Moss & Kopelman 2003). Survival from onset of symptoms is approximately 5–10 years (Hodges *et al.* 2003), and the underlying histopathology is very varied (Pick cells, motor neurone inclusions, non-specific changes) (Hodges *et al.* 2004).

In *normal ageing*, there are commonly memory impairments and the relationship between these and dementia has long been controversial. Huppert (1994) reviewed the attempts made to specify those aspects of memory most vulnerable to the ageing process, and the difficulty in generalising about the pathological substrates that might be responsible. In normal ageing, the impairments involve working memory or a lack of 'processing resources', so that performing a concurrent task while memorising is particularly difficult, and there are also particular problems in prospective memory (remembering to do something) and in remembering the contextual aspects of information (Huppert 1994; Parkin 1987). Dementia may represent accelerated ageing (Drachman *et al.* 1990) or it may represent a qualitatively distinct neuropsychological and neuropathological process superimposed on normal ageing (Huppert & Kopelman 1989). In recent years, the term 'mild cognitive impairment' has been used to describe elderly people with mild memory complaints associated with a moderate degree of hippocampal atrophy. If cases of mild vascular change, alcohol abuse, head injury or depression are rigorously excluded, there is now evidence that many of these cases 'convert' eventually to dementia (Lambon *et al.* 2003).

The pathological changes characteristic of ageing commonly involve the frontal and temporal lobes, but they are usually diffuse so that attribution of all the changes of normal ageing to, for example, frontal lobe or hippocampal atrophy is somewhat simplistic.

Psychogenic amnesia

Psychogenic amnesia is commonly either dense and global or restricted to circumscribed ('situation-specific') themes or events. When global it involves the blotting out of long periods or the whole of a person's past life, or even loss of personal identity. Amnesias of this severity do not occur in organic states unless at the same time there is abundant evidence of disturbance of consciousness or of severe disruption of cognitive functions generally. Interestingly, even with dense psychogenic amnesias there may sometimes be 'islands' of preserved memories that can be uncovered by careful questioning (Schacter *et al.* 1982). Inconsistencies in the account may also be noted. The subject with hysterical amnesia, for example, may insist that certain events could not have occurred during the period covered by the amnesic gap, while at the same time he is in no position to refute the proposition. More restricted (situation-specific) psychogenic amnesias will usually be found to centre on a traumatic event or circumscribed areas such as sexual abuse in childhood. Repeated episodes of psychogenic amnesia will frequently betray stereotyped themes or settings.

Psychogenic amnesia should be suspected when from the outset profound difficulty with retrieval of past events is coupled with normal ability to retain new information, and when there is an acute onset of memory loss for the entirety of a person's past. A delayed onset of the forgetting, e.g. following a minor head injury, is likewise sometimes seen in psychogenic but not in neurological amnesias. The focal retrograde amnesia syndrome has often been reported to arise in such circumstances, but its aetiology remains controversial (Kopelman 2000; Kapur 2000).

Kopelman (2002) discussed factors that appear to predispose to psychogenic amnesia, notably a severe precipitating stress, depressed mood or the experience of an earlier neurological amnesia in disorders such as head injury, epilepsy or alcoholism. In medicolegal practice, amnesia is often reported by offenders particularly in cases of homicide, occurring in 30–40% of cases, but is sometimes described in connection with other violent and non-violent offences. The amnesic episodes are typically fairly brief and knowledge of personal identity usually remains intact (Pyszora *et al.* 2003). Victims of offences such as rape (Mechanic *et al.* 1998) report similar amnesic gaps, and eyewitnesses of crime frequently make memory errors.

Special difficulties arise when neurological and psychological predisposing factors occur together. Psychogenic factors may sometimes be obtrusive in amnesias which are

clearly due primarily to brain damage, or a neurological deficit may come to be selectively reinforced or perpetuated on a psychogenic basis. Such difficulties are well illustrated by the celebrated dispute, reviewed by Zangwill (1967), that surrounded the Grünthal–Störing case for more than 30 years. Kopelman *et al.* (1994) described a patient with transient epileptic amnesia who had previously been diagnosed as having a psychogenic fugue. In focal retrograde amnesia, however, the faulty attribution may be to neurological causation, and psychological factors have sometimes been neglected or ignored.

Possible mechanisms in psychogenic amnesia

The mechanisms may vary from case to case. Faulty encoding of information may explain some examples, as discussed below, while others may represent 'motivated forgetting', 'dissociation' or 'repression'. Another possibility is of a primary retrieval deficit reflecting mood-dependent phenomena. Sometimes there may indeed be a substrate in transient neurological memory dysfunction which dictates the form the psychogenic reaction takes, as in the alcoholic patient reported by Gudjonsson and Taylor (1985).

Certain cases of psychogenic amnesia may depend, at least in part, on failure in the initial processing of experience rather than on a process of forgetting or repression (Kopelman 1985b, 1987b). Thus Taylor and Kopelman (1984) found that inability to recall a criminal offence was frequent when this had been committed in a state of very high emotional arousal, in the context of florid psychotic delusions, or under heavy alcoholic intoxication. All such factors would be liable to impair normal registration of what was happening at the time. On the other hand, Pyszora *et al.* (2003) found that in a sizeable proportion of offenders amnesic for their crime, the amnesic gap diminishes substantially through time, leaving only a brief (1 minute or less) permanent amnesia for the actual killing. In such cases, there was evidence that dissociative mechanisms may have been important in the aetiology of the amnesia.

The neuropsychology of psychogenic amnesia can resemble, in certain respects, that seen following head trauma. As already mentioned, there may be 'islands' or fragments of preserved memory within the amnesic gap, which are often described as strange and unfamiliar. Performance at verbal learning tests is variable: it has been reported as unaffected, mildly affected or more severely impaired in different studies. Memory for procedural skills is often preserved, and this may also be true of other aspects of implicit memory, such as tests of priming, although there are again conflicting reports. Deliberate cueing of memories is seldom successful, but memory recovery is often facilitated by chance cues in the environment. For example, a patient, on seeing an author's name on the spine of a book, recalled that he had a friend of that name who was dying of cancer. On transfer to a psychiatric ward, he recollected the details of another psychiatric hospital admission years earlier.

Some functional imaging studies have produced evidence of changes in brain regions analogous to those purported to be implicated in neurological retrograde amnesia (Markowitsch *et al.* 1997; Glisky *et al.* 2004), although in general these studies find decreased frontal activations. Anderson and Green (2001) reported evidence that executive mechanisms can be recruited to prevent unwanted memories from entering awareness, and that repeated use of such strategies inhibits the subsequent recall of the suppressed memories. More particularly, Anderson *et al.* (2004) showed that this memory suppression is associated with *increased* activations in dorso-lateral frontal cortex bilaterally, and with *diminished* bilateral activation in the hippocampi and the frontal poles. Hence, there is evidence that frontal executive mechanisms are implicated in psychogenic amnesia, but there are conflicting reports about whether this is correlated with increased or decreased frontal activation.

Memory disorder in the psychoses

While it used to be held that memory disorder was the hallmark of neurological brain damage, there are now indications that memory may also be defective in the psychoses. At an anecdotal level it is commonly noted that patients lack detailed knowledge of key features of their abnormal beliefs and experiences on recovery from schizophrenia or severe affective disorder. Moreover, depression has been shown to have a marked effect on the selective processes normally operative in memory, leading to readier recall and more accurate recognition of unpleasant compared with pleasant material (Lloyd & Lishman 1975; Dunbar & Lishman 1984; Teasdale & Spencer 1984). Among normal subjects such selectivity operates in the reverse direction.

However, there is also evidence that overall memory efficiency is impaired in patients with depression or schizophrenia. Cutting (1979) examined groups of patients with acute schizophrenia, chronic schizophrenia or major depression, and compared their memory test performance with normal subjects and with patients who had 'organic psychosyndromes'. The most prominent finding was that patients with chronic schizophrenia were impaired on verbal learning and pattern recognition tasks, their performance sometimes being comparable to patients with confusional states, dementia or Korsakoff's syndrome. The depressives were also impaired on both tasks but to a less marked degree. Acute schizophrenic patients performed poorly on verbal memory alone. It seemed unlikely that coincidental brain damage could be the explanation, but the possible effects of medication were harder to discount.

McKenna *et al.* (1990) evaluated a large group of acute and chronic schizophrenic patients on the Rivermead Behavioural Memory Test battery (Wilson *et al.* 1985) and found that poor performance was common and sometimes substantial. The level of memory impairment appeared occasionally to approach that of patients with overt brain damage. Tamlyn *et al.* (1992) confirmed such deficits in a more detailed

neuropsychological study of the same sample, finding that the pattern of impairment was similar to that of the classic amnesic syndrome. However, virtually all the patients were receiving neuroleptic medication and many were also taking anticholinergic drugs, which might have contributed to their poor performance. Saykin *et al.* (1991) demonstrated a disproportionate and apparently selective deficit on memory and learning tasks in 36 non-medicated acute schizophrenic patients.

Duffy and O'Carroll (1994) have reported a detailed study of 40 schizophrenic patients using the Rivermead Behavioural Memory Test battery, paired associate learning, and other memory tests. This was a heterogeneous sample of acute and chronic patients, all screened to exclude those with a history of alcohol or drug abuse, head injury or other brain disease. Poor performance was demonstrated on several tests: on the Rivermead battery the group was as likely to show significant memory impairment as the brain-damaged sample on which the battery was originally validated. The severity of impairment was related to age and to the chronicity of illness, but not to measures of motivation, severity of psychotic symptoms or amount of neuroleptic medication. Of particular interest were comparisons with a group of chronic Korsakoff patients. On tests of episodic memory the schizophrenics were considerably less impaired than the Korsakoff patients, only 50% of the schizophrenics scoring within the severely impaired range, but on a test of semantic memory (judgements of whether a series of factual sentences were true or false) they were significantly worse. McKenna *et al.* (1995) provided a detailed review of research into this and other aspects of memory in the disorder, including impaired episodic memory and spared procedural memory, analogous to findings in neurological amnesia (see Clinical picture and pattern of neuropsychological deficits in amnesia, earlier).

Disorders of language and the aphasias

Disturbance of language is an important source of evidence of focal brain disorder and, indeed, historically provided the chief impetus for attempts at correlating focal psychological deficits with regional brain pathology. Aphasic symptoms probably remain more useful clinically than any other cognitive defect in indicating the approximate site of brain pathology. (The term 'aphasia' and its derivatives is used in preference to dysphasia in line with growing convention in neuropsychological and linguistic circles but encompasses all varieties and severities of language disturbance.) Yet despite over 100 years of careful enquiry and observation the analysis of aphasia remains a controversial area, and beyond certain broad limits its relationship to regional cerebral disorder remains in many respects uncertain. This should not be surprising in view of the complex interrelationships that exist between different aspects of language processes, and the intimate way in which language

must enter into many other cognitive functions and vice versa. The parts of the brain concerned with language are extensive, and necessarily diffused over a considerable territory so that auditory, visual and motor mechanisms can be subserved. Consequently cerebral lesions that produce aphasia can lead to many forms of deficit, and at the same time to other defects which render the appraisal of clinico-pathological correlations difficult. Moreover, it is likely that there is individual variation in the anatomical substrate for language.

Cerebral dominance for language

The earliest observation of a relationship between anatomy and psychology to gain universal acceptance was that aphasia was overwhelmingly more common after lesions of the left hemisphere than the right. Later, right hemisphere lesions were reported to produce aphasia in left-handed subjects, and the general rule was proposed that the hemisphere contralateral to handedness governed speech. This has been upheld in large measure where right-handed subjects are concerned; the vast majority of cases of aphasia in right-handed subjects arise following lesions in the left hemisphere whereas the incidence is only about 1% when the lesion is right sided. However, it is now known from large unselected series of patients with brain lesions that left-handers also suffer aphasia more often from left than from right hemisphere lesions ('crossed aphasia'), in fact in a ratio of approximately 2:1. Bilateral speech representation appears to be more common in left-handers than right-handers, though remaining rare in both.

The most direct confirmation of these relationships has come from observing the transient effect on speech of injecting amobarbital into the carotid arteries of the left and right sides separately by the Wada technique (Wada & Rasmussen 1960; Rasmussen & Milner 1977). Amobarbital, 175 mg as a 10% solution, is injected over 2–3 seconds into the internal carotid artery. This results in a contralateral flaccid paralysis lasting several minutes during which the preservation or disruption of language can be briefly assessed. Rasmussen and Milner (1977) have reported 396 epileptic patients examined under such conditions. Among the right-handers 92% were found to have left hemisphere speech, 6% to have right hemisphere speech and in 2% there was bilateral representation. Among left-handers and ambidextrous patients (without early brain damage) 70% had left hemisphere speech, 15% right hemisphere speech and 15% had bilateral speech representation. In subjects with evidence of bilateral speech representation the speech defects were mild, from both the right- and left-sided injections. Functional MRI has begun to be used as a non-invasive method for determining cerebral dominance prior to surgery.

An alternative method for assessing language laterality applicable to clinical and non-clinical groups involves the

use of dichotic listening. Verbal information in the form of, for example, consonant–vowel syllables is fed through earphones to the two ears, but in such a way that different information arrives at each ear simultaneously. The subject must report whatever he hears, and is found to report more accurately and comprehensively from the ear contralateral to the hemisphere subserving language, the so-called right ear advantage in right-handed subjects. The results are less clear-cut than with the Wada technique, but dichotic listening has the advantage of safety and lack of adverse effects.

The prevalence of handedness in the normal population varies according to how it is defined and measured. Nevertheless if asked which hand an individual habitually writes with, about 90% of people will say the right. Dominance for other skilled tasks, footedness and eyedness yield lower percentages. The proportion of left-handers is slightly but consistently higher in males than females. Cultural factors exert some influence over these figures: the performance of certain tasks with the left hand is taboo in some societies and pressure from educationalists, particularly in the first half of the twentieth century, forced many children to write with their right hands regardless of their preference. While it is generally agreed that genetic factors are the major determinant of handedness, there remains controversy regarding the precise mode of transmission and genetic model. Of neuropsychiatric interest is the issue of 'pathological left-handedness'. It has been suggested that a proportion of people become left-handed because of early damage to their left hemispheres that brings about a shift in cerebral dominance. The age of 10–12 years is generally accepted as the upper limit beyond which brain damage will not alter handedness and beyond which the second hemisphere will not develop fully adequate language skills by way of compensation. That shifts in cerebral dominance do occur in relation to early left hemisphere damage is strongly upheld by Rasmussen and Milner's (1977) results of intracarotid amobarbital injection already mentioned above. Where left-handedness or ambidexterity was accompanied by a history of early left hemisphere damage there was, in contrast to all other groups, a large percentage of cases with language representation in the right hemisphere (28% left hemisphere speech, 53% right hemisphere speech, 19% bilateral speech representation). From a population perspective it has been estimated that only about 1 in 20 left-handers is 'pathological'. Furthermore, a variety of non-specific developmental disorders and insults may increase the incidence of non-right-handedness, suggesting that this may be due to the failure of left hemisphere dominance for language to become established in the first place rather than it shifting.

Handedness, or more broadly laterality, has been investigated in relation to many psychiatric disorders but most particularly schizophrenia (see Structural brain imaging, and also Associations with regional brain pathology, later) where it has been shown that non-right-handedness is indeed more

common. This appears to be due to an increase in left-handedness as well as mixed or 'ambiguous' handedness. Again, the finding is open to interpretation but is consistent with theories which postulate an abnormality in left hemisphere specialisation during development (Dragovic & Hammond 2005).

Yakovlev and Rakic (1966) reported that in fetal and newborn brains the corticospinal tract from the left hemisphere usually begins to decussate higher in the medulla than that coming from the right, and the corticospinal tract is usually larger on the right side of the cord than the left. Right hand preference, therefore, probably develops on the basis of the increased motor innervation available to the right side of the body. More directly, Geschwind and Levitsky (1968) examined 100 adult human brains at post-mortem and reported marked differences between the two hemispheres in the size of the planum temporale, which lies on the superior surface of the temporal lobe immediately behind Heschl's gyrus. This is the region that contains the auditory association cortex, and represents the classic Wernicke's area known to be important for language. Other related anatomical differences have been noted, for example the occipital lobe is usually wider on the left than the right, whereas the frontal lobe is wider on the right than the left; these asymmetries may be less striking or even reversed in left-handers. MRI has superseded post-mortem studies of laterality. A meta-analysis of all such anatomical data including MRI confirmed the left greater than right surface area and volume of the planum and different configuration of the left versus the right sylvian fissure in neurologically intact participants totalling several hundreds (Shapleske *et al.* 1999).

Evidence with regard to cerebral dominance for language has also come from observations after section of the corpus callosum for the relief of intractable epilepsy (Sperry 1966; Gazzaniga & Sperry 1967; Sperry & Gazzaniga 1967). As a result of the operation the two hemispheres are virtually isolated from each other and information can be fed tachistoscopically to either hemisphere alone by brief exposures in the opposite half-field of vision. When a picture of an object is exposed to the dominant hemisphere it can be named promptly or recorded in writing, but similar exposures to the non-dominant hemisphere meet with no such response. If pressed to answer after information has been fed to the non-dominant hemisphere, the patient may deny seeing anything, or alternatively the speaking hemisphere may resort to pure guesswork and produce a random response. Nonetheless, the patient can select the appropriate matching object, by means of palpation with the left hand, from among a group of objects concealed behind a screen, indicating that the non-dominant hemisphere has correctly perceived the picture despite the patient's inability to name it. In a similar way an object concealed from view can be named when palpated by the right hand but not when palpated by the left

hand. The non-dominant hemisphere is therefore mute as would have been expected.

In some of these patients, however, it seems certain that limited comprehension of language can take place in the non-dominant hemisphere. The left hand can correctly select or point to an object which corresponds to a name exposed briefly to the non-dominant hemisphere alone. That the dominant hemisphere can have played no part is shown by the failure of the right hand to perform accurately in this situation; moreover the subject cannot name the matching object if this has been selected by the left hand but remains concealed from view. Auditory comprehension can be demonstrated by flashing a picture to the non-dominant hemisphere and then asking the patient to signal when the matching word is read aloud to him; this he can do by signalling with the left hand but not with the right. Alternatively, a word can be spoken out loud and the patient asked to signal when the corresponding printed word is exposed visually to the non-dominant hemisphere. Ingenious research techniques that overcome the limitations of brief tachistoscopic presentations have allowed further exploration of the language capacities of the non-dominant hemisphere (Zaidel 1977, 1978; Gazzaniga 1983). It has become apparent that such capacities are present in a small proportion of patients. The degree of sophistication varies widely, from primitive levels of comprehension to the ability to detect semantic incongruities in sentences and to understand syntactic rules. It is *expressive* speech that appears to be most outside the capabilities of the normal right hemisphere as does normal inferential reasoning (Gazzaniga 1985).

Some exceedingly rare observations have been made on patients after total surgical removal of the dominant hemisphere. One such patient was investigated by Smith (1966) after left hemispherectomy for recurrence of a glioblastoma. The patient had previously been strongly right-handed. In the immediate postoperative period there was, as expected, a severe sensory and motor dysphasia along with right hemiplegia and hemianopia. Even then, however, he could follow some simple commands, indicating some preservation of comprehension of speech. He could also utter emotional expletives such as 'Goddamit' with good articulation, at a time when single words could not be repeated and when there was no ability at all to communicate in propositional speech. Suddenly in the tenth postoperative week he asked his nurse 'What does "B.M." mean?' in response to her enquiry about his bowel movements. Thereafter the occasional use of fragments of propositional speech increased, along with ability to repeat progressively longer sentences on command, though most of the time the patient remained incapable of speaking voluntarily. Comprehension of speech, in contrast, appeared to reach approximately

normal levels at 1 year postoperatively before the tumour recurred (Smith 1972). Of particular interest in view of the evidence linking musical functions with the minor hemisphere (see Auditory agnosia and auditory perceptual defects, later) was the patient's eventual ability to sing familiar songs and hymns with little hesitation and few errors of articulation, even though speaking remained very severely impaired. A remarkably similar postoperative course has been documented in a second patient (Burklund & Smith 1977). Other scattered examples in the literature are reviewed by Searleman (1977).

The rarity of such cases again makes it difficult to estimate how far the results may have been due to an unusual degree of bilaterality of language already present before operation, or how far new capacities to organise language were developed in the non-dominant hemisphere. The complex effects of hemispherectomy on language development following brain damage in childhood are described by Vargha-Khadem *et al.* (1991). A profile of right hemisphere language has been summarised as follows: reduced auditory-verbal short-term memory, better comprehension of speech than reading, and rudimentary phonology (affecting all tasks requiring grapheme-phoneme conversion).

Finally, there is now considerable evidence that the affective components of language, including prosody and emotional gesturing, appreciation of humour and metaphor, are the special prerogative of the right hemisphere (Ross & Mesulam 1979; Ross 1981; Benson & Zaidel 1985). Thus patients with right hemisphere strokes may lose the ability to express emotion by voice or gesture, or to perceive the affective colouring in the speech or gestures of others, while formal propositional aspects of language remain intact. Indeed, Ross (1981) suggests that the functional organisation of the affective components of language in the right hemisphere may closely mirror that of propositional language in the left, and has produced evidence of a similar range of 'aprosodic' subsyndromes to that encountered among the aphasias (motor aprosodia, sensory aprosodia, etc.).

The concept of 'auditory affective agnosia' in relation to language is considered later in the chapter (see under Auditory agnosia and auditory perceptual defects).

Localisation of language functions within the brain

We have little direct knowledge about the physiological mechanisms that underlie language functions in the healthy intact brain. Since language is unique to humans there is no paradigm which can be studied in animals, and evidence has had to accumulate slowly from the study of the damaged human brain. Inferences about normal function from studies of abnormal function are notoriously dangerous, and not

surprisingly numerous theories abound on psychological, physiological and anatomical levels. It is, however, useful to have a framework against which to view the phenomena of aphasia, and the theoretical background is therefore briefly reviewed before the clinical data are considered.

Early and primitive localisationist views postulated 'speech centres' for speaking, reading and writing, proposed by Lichtheim and Wernicke in the 1880s, which contained the repositories for word images and which could be disturbed either directly by lesions or by damage to various connecting pathways. Freud was one of the first to attack the 'diagram makers' and propose a more holistic view of the functions of the speech territory in the dominant hemisphere. Head further developed the dynamic concepts of Hughlings Jackson and proposed a classification that depended primarily on symptoms of deficit rather than locus of lesion. However, as noted above, there has been a resurgence of interest in those very diagrams which lend themselves to the information processing models favoured by contemporary cognitive neuropsychologists (Ellis and Young 1988). Indeed, the so-called Wernicke-Lichtheim model does rather well at making sense of disorders of spoken language and forms the basis of a useful classificatory scheme (see below). Disorders of across-language modalities have proved less tractable.

The classification of the aphasias must be seen in the light of the distinct aims of the clinician and the psycholinguist. The clinician is trained to recognise syndromes, collections of symptoms and signs that frequently cluster together. A syndrome so defined, if it is to have any utility, can then be related to aetiology, prognosis and possibly pathophysiology including anatomical localisation. Such syndromes tend to arise through the astute observational skills of an experienced clinician. Hence Broca's aphasia, a non-fluent disorder of the motoric aspects of speech with relative preservation of comprehension. The aetiology is often an occlusion of the left middle cerebral artery leading to an infarct of the lateral inferior frontal lobe. However, to the linguist or cognitive neuropsychologist, the pathology is of only peripheral interest in comparison to the nature of the language disorder itself. The non-fluency may be characterised more precisely as a reflection of 'agrammatism', the loss of syntactic structures or 'function words' linking verbs and nouns, such as prepositions, conjunctions and auxiliary verbs. This loss gives speech a telegraphic quality which nevertheless conveys meaning. It is the nature of the pure cognitive deficit that is of interest to the linguist and not the 'accidentally' coexistent features of the syndrome. Since comprehension, reading or writing may not be similarly affected, the cognitively minded observer argues that their presence or absence is not essential to the disorder and so can be set aside; if deficits were present in these modalities, it might point to a problem at the 'deeper' semantic level. Contrast this with the clinician, particularly the neurologist, who may use just such secondary aspects of the syndrome including even non-linguistic aspects such as

a right Babinski reflex to form an impression of the extent of the patient's lesion as it affects the left hemisphere, possible causes and likely prognosis. Yet there is no psychological connection between retrieval of function words and extension of the great toe! The clinician is looking for the presence of associations between clinical features that have been noted by others to co-occur and which are probabilistic and can be supported by epidemiological evidence; the cognitive neuropsychologist is looking for patterns of deficits and abilities which relate to a theoretical model.

As a result of the above, classification of the aphasias can be confusing as it tries to represent these differing perspectives. The pure cognitive or linguistic account will tend to group language deficits according to the level of abnormality along the hierarchy shown below.

- Phonology (or orthography): the basic 'building blocks' of speech (written words).
- Syntax: the rules governing the grammatical forms of words and connections between words in sentences.
- Lexical semantics: word meaning.
- Pragmatics: to do with the intended meaning of language and conventional usage.

The broadest and most simplistic clinical classification is between motor, non-fluent, expressive Broca's aphasia on the one hand and sensory, fluent, receptive Wernicke's aphasia on the other. The Wernicke–Lichtheim model allows for these two broad types of language disorder, which are lesions to the motor word-representation and auditory word-representation centres respectively, the hypothetical centres sitting comfortably on defined neuroanatomical areas. Furthermore, the model both predicts and provides a framework to explain other language problems such as conduction aphasia (failure of repetition) and what became known as the transcortical aphasias in which repetition is preserved. Writing and reading are not included in this scheme. While a serious omission, this also reflects clinical practice at the bedside which, rightly or wrongly, tends to concentrate on spoken language.

Geschwind (1967) was an important heir to the likes of Wernicke and expanded the model to account for language in general, based on the learning and arousal of associative links. He pointed out that the distinctive element in human language, which is not present in animal communication, derives from our ability to form higher-order associations between one sensory stimulus and another. In subhuman primates the principal outflow from sensory association areas is to the limbic system, enabling the animal to learn which stimuli have importance with regard to drives for food, sex or aggression; interconnections between the sensory association regions for different sensory modalities are meagre by comparison. The impressive advance in the human brain lies in the expansion of the zone in the region of the angular gyrus at the junction of the temporal, parietal and occipital lobes, an area strategically situated with respect

to the association cortices for hearing, touch and vision (heteromodal cortex). It is noteworthy that inputs to this part of the brain are almost exclusively from other cortical regions, and furthermore that it is one of the last brain regions to myelinate during development.

Neuroimaging and language

In general, structural neuroimaging has tended to support the traditional syndrome localisations for the main subvarieties (Broca's, Wernicke's and conduction aphasias), likewise for the principal subdivisions of alexia and agraphia (Benson & Ardila 1996). A large MRI study (Kreisler *et al.* 2000) examined 107 stroke patients and found that non-fluent disorders tended to be associated with frontal and putaminal lesions, repetition disorders to lesions of the insula–external capsule. Disorders of comprehension invariably involved lesions of the posterior parts of the temporal gyri, while fluent disorders with paraphasias were found with temporal lobe lesions with extension subcortically. Similarly, Bates *et al.* (2003) used a voxel-based method of matching MRI data with aphasia symptoms in 101 aphasic stroke patients and found that lesions within the left insula and deep parietal white matter affected fluency while more posterior lesions in the left middle temporal gyrus had the most impact on auditory comprehension (Fig. 2.1: see also Plate 2.1).

Such analyses shift between discussion of say 'Broca's area' as a fixed anatomical entity and as a theoretical construct. As neurologist Richard Wise (2003) concludes, neuroimaging allows more precise lesion location at the time of patient testing than was possible in the past and, as a result, syndromes have been described that may be associated with lesions at various locations. Rather than this being the result of individual differences, he suggests that it is likely that 'broadly similar clinical syndromes may result from very differently sited cortical, subcortical or tract lesions within distributed neural systems that are essentially similar between subjects'.

Non-invasive functional neuroimaging studies using PET and fMRI have contributed a great deal to illuminating the brain regions involved in language processing in the intact brain.

In what is now regarded as a classic study, Petersen *et al.* (1988) used PET to explore linguistic functions in an interesting experimental paradigm. Seventeen right-handed normal volunteers were given repeated brief PET scans, using ^{15}O -labelled water, under a succession of experimental conditions arranged hierarchically. By subtraction, the effects of each extra task demand on regional cerebral blood flow could be discerned. In the first comparison nouns were presented (visually or auditorily) without task demands, and compared with a control state of simple visual fixation. Involuntary word-form processing was targeted by this subtraction. Next the subject was required to speak each word, revealing areas involved in output coding and motor control. Finally, the subject was asked to give a use for each presented

Fig. 2.1 Representative slices from VLSM maps computed for fluency and auditory comprehension performance of 101 aphasic stroke patients.

These maps are depictions of *t*-test results evaluating patients' performance on a voxel-by-voxel basis, for fluency (a–c) or auditory comprehension (d–f). High scores indicate that lesions to these voxels have a highly significant effect on behaviour. Low scores indicate that the lesions had relatively little impact on behaviour. From Bates *et al.* (2003), *Nature Neuroscience* **6**, 448–450. See also Plate 2.1.

word, revealing the cerebral substrate for noun–verb associations (semantic processing).

This work has been replicated and extended in numerous experiments since. Functional MRI has overtaken PET as the methodology of choice for functional neuroimaging and the combined body of work from both has been well reviewed for the general reader (Price 2000; Small and Burton 2002).

However, functional imaging techniques have shown additional complexities, revealing areas of hypometabolism extending beyond or even distant from the areas of known structural damage. Metter and Hanson (1994), for example, report PET studies which show that hypometabolism in the left temporoparietal cortex appears to be critical for the development of aphasia, being present in all the aphasics they studied irrespective of the location of structural damage. Recent work has attempted to shed light on the processes of recovery (Price & Crinion 2005): it appears that recovery of speech correlates with slowly evolving ipsilesional (left hemisphere) changes in activation. Right hemisphere homologous activation after, for example, left anterior hemisphere aphasia-producing stroke does not seem to correlate with recovery or preservation, so appears to be a reflection of non-functional (in the linguistic sense) changes. In terms of speech comprehension, the picture is more mixed and it seems that both the right and left temporal lobes contribute to recovery.

Clinical syndromes of language impairment

For the purposes of clinical evaluation it is useful to consider a broad division into defective understanding of speech or written material, and defective production of speech or

writing. However, the great majority of patients with language disturbance show a complicated mixture of deficits.

For an extended presentation and discussion of the various disorders, Benson and Ardila (1996) should be consulted. At least partial support for the principal subvarieties and their anatomical localisation has come from neuroimaging studies, but with the caveats given by Wise and others. The syndromes outlined below are clearly to a considerable extent abstractions from a very complex whole.

Broca's aphasia (cortical motor aphasia, expressive aphasia)

The primary defect is on the effector side of speech, thus involving the mechanisms by which words are chosen and articulated and sentences constructed. Unlike pure word-dumbness, however, writing is affected in parallel with speaking, and while comprehension is relatively intact there may be difficulty in carrying out complex instructions. This may be on account of apraxia or because the instructions require complex internal verbalisation for their efficient execution.

Speech is characteristically sparse, slow and hesitant, with marked disturbances of rhythm, inflexion and articulation, unlike the fluent expressive speech of primary sensory dysphasia. Moreover, the patient is clearly under stress while trying to speak. Word-finding provides obvious difficulty, wrong words are often chosen and the words that are chosen are often mispronounced. Marked reiteration and perseveration are common. However, the patient usually recognises his mistakes, attempts to correct them and becomes impatient about them. Moreover, he can select the correct word

when this is offered to him. There is a marked impairment of syntax (agrammatism; see under Localisation of language functions within the brain, earlier). This further impairs the patient's ability to transmit meaning. He often tries to compensate for his speech defects by means of pantomime and gesture, all again in contrast to the patient with primary sensory dysphasia.

The phrase length is short, and the style may be abbreviated and 'telegraphic' with omissions of words, but the speech that does emerge is meaningful. Ability to repeat what the examiner says to him may be an improvement on what the patient can produce spontaneously, but nevertheless is always profoundly impaired. In the most severe examples the patient may have only one or two words at his command, or there may be stereotyped repetition of some word or phrase (reiteration or 'recurring utterance'). However, total loss of ability to speak is not seen, and an occasional speech sound can usually be discerned.

Among these marked expressive difficulties it may be noted that the automatic repetition of serials, such as numbers or days of the week, is relatively well preserved even though they are not well articulated. If such lists are well articulated, an apraxia of speech may be suspected (see below). Also, in severe cases, emotional ejaculations may be surprisingly intact when voluntary utterance is reduced to the minimum. Sometimes an object exposed to view can be named when the same name cannot be found in spontaneous speech. Similarly, a habitual situation may call forth a word such as 'goodbye' when the patient is quite unable to produce it on request.

Comprehension of written and spoken instructions may be relatively intact but is rarely normal. Particular difficulty is encountered over the comprehension of grammatically significant structures. Quite often the patient may be well aware of the meaning of a word that he reads even though he cannot pronounce it aloud. Reading out loud will show a halting jerky flow, with slurring and occasional mispronunciations. Disturbances of writing may be closely similar to those of speaking. The lesion is in the posterior two-thirds of the third frontal convolution, i.e. the pars triangularis and operculum of the premotor cortex, the classic Broca's area. Sometimes this extends also onto the lower part of the precentral convolution.

Wernicke's aphasia (primary sensory/receptive aphasia)

The primary deficit is in the comprehension of spoken speech. There is defective appreciation of the meaning of words and in particular of meaning conveyed by grammatical relations. The patient has corresponding difficulty in repeating what is said to him and in responding to commands. In less severe examples the difficulty in responding to commands can be observed to increase with the complexity of instructions, though interestingly quite complex

'whole-body' commands can prove to be surprisingly well performed (Benson & Geschwind 1971). Other aspects of hearing are intact, as with pure word-deafness, but unlike the latter there are also impairments of spontaneous speech, writing and reading. These added difficulties are attributable to the fact that the cortical mechanisms for analysing incoming speech are directly implicated by the lesion, not merely cut off from input as in pure word-deafness.

Thus ability to speak is also impaired, presumably because auditory associations or schemata must first be aroused before the efferent speech mechanisms can produce speech in a normal manner. In this way the terms 'receptive' or 'sensory' may be misleading. Words are used wrongly, paraphasic errors and neologisms are frequent, and sentences tend to be poorly constructed with errors of grammar and syntax. However, the faulty speech is produced fluently and without effort. Normal rhythm and inflexion are preserved and there are no articulatory defects. The speech may even be excessive in flow or under pressure, perhaps because the effector mechanisms 'run on' to a large degree autonomously when freed from the control of higher functional levels.

A patient reported by Brain (1965) responded as follows. When asked 'Do you have headaches?' he replied 'No. I've been fort in that way. I haven't been headache troubled not for a long time.' When shown a picture of an elephant he was unable to name it, but pointed to the mouth and said 'That's his sound, he is making his sound – seems to have got his voice opened there'. When shown a picture of a penguin he said 'A kind of little ver (bird) – machinery – a kind of animal do for making a sound'. When shown a tape measure he called it 'A kind of machinery', and when immediately afterwards shown a bunch of keys and asked to name it he said 'Indication of measurement of piece of apparatus or intimating the cost of apparatus in various forms'.

Reiterative errors are obvious in the above example, in that the speech is contaminated by words which the patient has once used but then cannot easily discard. The patient is usually unaware of his mistakes and makes no attempt to correct them. Unlike the patient with nominal aphasia (see below) he is often unable to recognise the correct name for an object when this is told to him.

Reading and writing are also impaired since these are presumably also dependent on the cortical areas involved in comprehending spoken speech (and developmentally they are learned in association with spoken language). Single words may be read aloud correctly, but reading out of sentences becomes jumbled and contaminated by paraphasic errors. Written instructions, even if correctly read, may not be carried out, indicating that the patient has failed to

understand what he has read. Generally the degrees of disability in understanding spoken and written language parallel each other closely. The disturbances of writing also closely mirror those of spoken speech, except that a copious fluent flow is much less common in writing than in speaking.

The lesion is in the auditory association cortex of the superior and middle temporal gyri of the dominant hemisphere (Wernicke's area), presumably preventing the recoding of auditory messages for recognition, and debarring the arousal of auditory associations as a necessary step for reading, writing and the production of spoken speech.

Pure word-deafness (subcortical auditory aphasia, verbal auditory agnosia)

The patient can speak fluently and virtually without error, and similarly can write normally. He can also read and comprehend what he reads. The defect is restricted to the understanding of spoken speech, even though other aspects of hearing are intact. In fact the patient hears words as sounds but fails to recognise these sounds as words. Hemphill and Stengel's (1940) patient said 'Voice comes but no words. I can hear, sounds come, but words don't separate. There is no trouble at all with the sound. Sounds come. I can hear, but I cannot understand it.' As a result the patient cannot repeat words spoken to him and cannot write to dictation.

Such a defect can equally be regarded as an agnosia for spoken words. It is extremely rare, but there is general agreement that the lesion is in the dominant temporal lobe, closely adjacent to the primary receptive area for hearing, i.e. Heschl's gyrus of the first temporal convolution. Geschwind suggests that it is caused by interruption of the auditory pathway to the dominant temporal lobe together with a lesion of the corpus callosum. The patient can still hear because the auditory pathway to the non-dominant cortex is intact, but incoming auditory information cannot gain access to the speech-receiving mechanisms of the dominant lobe. The disorder is rare because a lesion in this situation will usually extend far enough to the surface to damage the speech-receiving mechanisms themselves, resulting in the more widespread disabilities of a primary sensory dysphasia.

Pure word-blindness (alexia without agraphia, agnosic alexia, subcortical visual aphasia, occipital alexia)

The patient can speak normally and has no difficulty with comprehension of the spoken word. His difficulties with language are entirely restricted to his understanding of what he reads. The patient can still describe or copy letters even though he cannot recognise them, showing that the defect is not due to loss of the visual images of the letters. Attempts at reading may betray a laborious letter-by-letter strategy. Some patients manage better with written script than printed material, presumably because they can more readily reproduce the letters in imagination with the right hand and

thereby obtain kinaesthetic cues. Occasionally, numbers continue to be recognised when letters are not, perhaps again via kinaesthetic cues that are derived from early associations between counting and manual activities.

The patient can write spontaneously and to dictation, though subsequently he cannot read what he has written. The writing is usually entirely normal, though it may contain minor errors of reduplication or misalignment of letters. He may be able to copy written material slowly and laboriously.

An almost invariable accompaniment is a right homonymous hemianopia. Colours cannot be named, even though colour perception can be shown to be intact by sorting tests. Here it is probably significant that colour naming represents a purely visual-verbal association process and cannot derive support from other cues. Essentially, word-blindness is a failure to recognise the language values of the visual patterns which make up words, although there is no disturbance of the symbolic function of the words themselves. This is confirmed when the patient can spell out loud and recognise words that are spelled out loud. The lesion is of the left visual cortex together with the splenium of the corpus callosum; thus visual input is possible only to the right hemisphere, and cannot gain access to the language systems of the left. It is therefore a disconnection syndrome par excellence. The situation is analogous to that of the lesion causing pure word-deafness. However, pure word-blindness is commoner because the lesion does not so readily impinge on the language areas themselves. The usual cause is occlusion of the left posterior cerebral artery.

Pure word-dumbness (apraxic anarthria, subcortical motor dysphasia, aphemias)

The patient can comprehend both spoken speech and written material without difficulty, and shows this by his ability to respond to complex commands. He can express himself normally in writing, which also serves to demonstrate that inner speech is perfectly preserved. The defect is restricted to the production of spoken speech, which is marked by slurring and dysarthria. The patient cannot speak normally at will, cannot repeat words heard and cannot read aloud. In severe cases he may be totally unable to articulate. Yet for other purposes the muscles of the tongue and lips function without impairment.

The condition may thus be regarded as an apraxia restricted to the movements required for speech. The exact site of pathology is uncertain, but the lesion is probably beneath the region of the insula, interrupting the pathway from the cortical centres responsible for motor schemata for words to the motor systems used in articulated speech. It is extremely rare because the lesion usually also involves the former at the same time, resulting in a primary motor dysphasia. It has been claimed that Broca's original patient 'Tan' in fact had apraxia of speech and that his lesion (a cystic tumour) centred

around the insula rather than what has become known as Broca's area (Dronkers *et al.* 1992).

Pure agraphia (agraphia without alexia)

Agraphia may accompany almost any form of generalised aphasia or be a component of generalised apraxia. As an isolated defect, however, it may be seen as the graphic equivalent of pure word-dumbness. Comprehension of written and spoken material is normal, and the patient's own speech is unimpaired. However, he is unable to write either spontaneously or to dictation, though he may fare rather better at the copying of written material.

Brain (1965) pointed out that writing is a considerably more complex process than articulated speech, since after the processes leading up to speech there must then be evocation of visual graphic schemata in the posterior parts of the brain, and of motor schemata in close relation to the motor cortex. The lesion in pure motor agraphia is thought to interrupt the pathway from the left angular gyrus to the hand area of the left motor cortex, and to lie usually in the second frontal gyrus anterior to the hand area or sometimes in the parietal lobe.

Nominal aphasia (amnesic aphasia, anomic aphasia)

Though this is one of the commonest forms of aphasia, it is the least understood in terms of pathophysiology. The principal difficulty lies in evoking names at will. This may vary from total inability to name any object on confrontation to a mild disorder demonstrable only where uncommon words are concerned. The patient can describe the object and give its use, even when the name eludes him, and like the patient with primary motor aphasia can usually recognise the correct name when this is offered to him. He can often use the same word without difficulty a moment later in spontaneous connected speech. Demonstration of knowledge of the concept behind the word in pure nominal aphasia is in contrast to the patient with semantic dementia, who has lost all the meanings attached to the word along with the word itself (see earlier in chapter under Amnesia in diffuse cerebral disease; also see Chapter 9: Frontotemporal dementia/Clinical features).

Conversational speech is fluent, with no difficulty in articulation and little or no paraphasic interference, but circumlocutions are used and word-finding pauses may be evident. 'Empty words' such as 'thing' or 'these' may be frequently employed, and there is a notable lack of substantive words. Otherwise, the grammatical structure of sentences is usually well preserved. The patient can repeat fluently what is said to him, and he usually performs relatively well on well-learned serials such as numbers or days of the week.

Comprehension is relatively preserved in most instances, but internal speech is often affected so there may be difficulty in understanding or executing some oral or written commands.

It is not generally agreed whether nominal dysphasia represents a distinct form of defect. Some view it merely as a

mild form of primary sensory aphasia, since with expanding lesions one may merge progressively into the other. This is the type of aphasia which in mild degree has most often been attributed to diffuse rather than focal brain damage. Certainly it may occur with diffuse brain dysfunction due to toxic or degenerative conditions. However, it may also be found with focal brain lesions, perhaps particularly (though not exclusively) with dominant temporoparietal lesions in the neighbourhood of the angular gyrus. Acaculia and other components of Gerstmann's syndrome often occur as associated deficits.

Conduction aphasia (central dysphasia, syntactical dysphasia)

Essentially, conduction aphasia consists of a grave disturbance of language function in which speech and writing are impaired in the manner described above for primary sensory dysphasia, but in which comprehension of spoken and written material is nonetheless relatively well preserved, as shown for example by simple yes/no responses. Repetition of speech is very severely impaired.

According to Geschwind it results from a lesion that spares both Wernicke's and Broca's areas but disrupts the major connections between them. Thus Wernicke's area can function relatively well in analysing incoming information, though it can no longer act to guide the patient's own productions. There are contending views about the site of the responsible lesion (see Benson & Ardila 1996). One view, which accounts for the essential features of the disorder, blames a lesion of the arcuate fasciculus as it passes from the temporal to the frontal lobe by way of the parietal lobe. The more the lesion comes to implicate Wernicke's area itself, the more will comprehension be impaired and the closer will the picture approximate to that of primary sensory aphasia.

The repetition defect in conduction aphasia has come under closer scrutiny recently. Patients who show a marked repetition defect for verbal material presented in the auditory modality appeared on analysis to have a selective impairment of the immediate memory span for auditory verbal material that was directly related to the 'memory' load of the task. (Note that we routinely test repetition when we carry out the digit span test, but regard it as a test of immediate or short-term memory.) There is much less difficulty when comparable material is presented visually. Moreover, auditory verbal learning and verbal long-term memory are relatively intact, indicating that material can nonetheless gain access to the long-term memory store.

Syndromes of the isolated speech area

Under this title Goldstein (1948) and Geschwind *et al.* (1968) describe further variants of aphasia, which though rare demand an alternative explanation in terms of mechanism. Comprehension is profoundly disturbed, but in contrast to

primary sensory dysphasia the patient can easily repeat what is said to him, and the ability to learn new verbal material is retained. Moreover, spontaneous speech is slow and laboured and lacks the fluency of primary sensory dysphasia. It is postulated that both Wernicke's and Broca's areas, and the connections between them, remain intact but the whole system is cut off from other parts of the cortex. It is the lack of these widespread connections that leads to impaired comprehension and defects of propositional speech.

Though in pure form the syndrome is extremely rare, two variants are well recognised. *Transcortical (or extrasylvian) motor aphasia* differs in that the patient can comprehend spoken speech, and is ascribed to a lesion anterior and/or superior to Broca's area, or in some cases in the supplementary area of the medial frontal cortex. *Transcortical (or extrasylvian) sensory aphasia* differs in that the fluency of output is preserved. Echolalia is often prominent. The facility with which the patient repeats the examiner's statements, and the fluent jumbled output of speech, stand in contrast to the patient's lack of comprehension. This may lead to misinterpretation of the syndrome as an acute psychotic disturbance, especially since obvious neurological deficits can be lacking (Benson & Ardila 1996). The lesion usually involves either the parieto-occipital or temporo-occipital border zone areas.

Aphasia and other aspects of intelligence

Opinion has differed about the extent to which aphasia can be regarded merely as 'loss of a linguistic tool' while other aspects of intellect remain intact. Language is, of course, an integral part of conceptual thinking and of problem-solving in many areas, but it may be that some aphasic patients retain in large degree the automatic and subconscious use of words in thinking processes. Impairment of the ordered perception of space or time may worsen aphasic difficulties, since a proper conception of such matters is essential for symbolic thought. Nevertheless, aspects of social cognition may remain highly attuned despite severe language impairments as may fine perceptual discriminations of people and places. The often difficult question of assessing legal competency in aphasic patients is discussed by Benson and Ardila (1996).

Subcortical aphasia

The possibility that subcortical pathology might contribute to, or even be responsible for, certain aphasic syndromes has a considerable history. Renewed attention has been directed to the issue now that neuroimaging is capable of revealing discrete subcortical infarcts, and certain syndromes such as 'thalamic' and 'striatal' aphasia have been proposed. Benson and Ardila (1996) review the still uncertain status of such syndromes, and the difficulty in deciding whether the language disturbance reflects the direct effects of the subcortical lesion or derives from distant effects induced elsewhere in the brain. Functional imaging techniques have shown that secondary involvement of cortical language areas is common,

presumably in consequence of 'diaschisis' subsequent to disruption of subcortical-cortical mechanisms (Perani *et al.* 1987). Instances of 'subcortical neglect' may similarly owe much to secondary effects on right hemisphere cortical activity.

The picture usually described is of mutism following an acute intracerebral haemorrhage, followed by hypophonia and slow amelodic output. This may evolve to a combination of severely paraphasic speech with relatively well-preserved capacity for repetition, which appears to be the characteristic pattern. The subcortical structures involved are virtually always situated in the hemisphere dominant for language.

Thalamic aphasia begins with mutism but generally changes to a fluent, paraphasic jargon output. Difficulty with naming is often dramatically severe, but comprehension and repetition are comparatively well preserved. In most cases the language disorder is transient, showing improvement over the course of weeks or months. The puzzling feature is the rarity of such a development among the considerable number of persons who develop thalamic lesions.

Striatal (striatocapsular) aphasia appears to derive chiefly from lesions of the putamen and internal capsule. The patients reported by Damasio *et al.* (1982a) had prominent involvement of the anterior limb of the capsule and also the head of the caudate nucleus. Speech remains sparse, fluent but hesitant, dysarthric and paraphasic, though again comprehension and repetition are usually good. The ability to name is better preserved than with thalamic dysphasia. Naeser *et al.* (1982) have pointed to subdivisions within the syndrome according to the precise site of the lesion and its extension into neighbouring territories. Perseveration was commonly associated with caudate lesions in the survey by Kreisler *et al.* (2000).

Alexia with agraphia (visual asymbolia, parietotemporal alexia)

The patient is unable to read as with pure word-blindness, but in addition he is unable to write. However, the execution and comprehension of spoken speech are substantially unimpaired.

The difficulty in reading is similar to that described for pure word-blindness. The difficulty in writing varies from complete inability to form letters to preservation of partial attempts at writing words. Copying is better than spontaneous writing, which is the converse of the situation in pure word-blindness. Moreover, the patient cannot understand words that are spelled out loud, revealing that he is truly illiterate, unlike the patient with pure word-blindness.

The condition may be the predominant symptom from the outset but this is rare. Usually it is found as the residual disturbance when a more global dysphasia clears up. It is usually accompanied by some degree of nominal dysphasia, dyscalculia, spatial disorganisation or visual object agnosia.

The defect results from disturbance of those parts of the brain which deal with the visual symbolic components of language. The lesion is usually extensive within the parietal or parietotemporal region of the dominant hemisphere, but the angular and supramarginal gyri are always involved.

Acquired alexias

The psycholinguistic classification of the dyslexias or alexias has been one of the successes of the cognitive neuropsychology approach (Shallice 1988). Intriguing forms of dyslexic error have been highlighted, for example in 'deep dyslexia' in which words are misread yet in a manner that betrays understanding at some level of their meaning (so-called 'semantic errors') (Marshall & Newcombe 1973). For example, 'dinner' may be read as 'food', 'close' as 'shut', or 'dog' as 'animal'. Such patients are unable to read even simple non-words and cannot 'sound them out'. Observations such as these have led to speculation and experimentation in attempts to clarify the various routes whereby the written word image is translated into meaning (Coltheart *et al.* 1987). Anatomically, patients with deep dyslexia tend to have extensive lesions, usually vascular, involving left perisylvian regions but extending into the frontal, parietal and temporal lobes. Hence additional language problems are common. The extent to which the intact right hemisphere might take on some of the left hemisphere's functions in this situation is hotly debated.

Phonological dyslexia is characterised by a selective impairment in the ability to read non-words but without the semantic errors of deep dyslexia. Anatomically, the lesions tend to involve the anterior perisylvian areas. In contrast 'surface dyslexia' is characterised by a tendency to read words according to how they ought to sound given grapheme-phoneme conversion rules (e.g. 'come' → 'comb', 'island' → 'izland'), known as regularisation errors. This pattern may be seen in semantic dementia. The responsible lesions tend to be left temporal, insula and putamen.

Developmental dyslexia (specific reading retardation)

Some children experience unusual difficulty in learning to read and to spell, despite normal or even superior intelligence and equivalent educational opportunities to their peers. The proportion so affected has varied in different surveys and according to the criteria employed, but has been judged to involve just under 4% of 10 year olds on the Isle of Wight compared with almost 10% in inner London boroughs (Rutter & Yule 1975). Such disorder has been labelled 'developmental dyslexia' or, alternatively, 'specific reading retardation' to distinguish it from the reading difficulties associated with generally poor intellectual endowment.

Important distinctions from the latter have emerged in group comparisons, including a threefold to fourfold preponderance in boys, an association with speech and language impairment as opposed to a wider range of developmental delays, and less frequent evidence of brain damage as judged from birth history, neurological examination or EEG (Rutter 1978; Maughan & Yule 1994). Rather strikingly, the Isle

of Wight study showed that children with specific reading retardation made significantly less progress with reading or spelling than children with 'general reading backwardness', between the ages of 10 and 14, despite their superior intelligence, whereas their progress with mathematics was superior as expected (Yule 1973; Rutter *et al.* 1976). Distinctions between the two groups have traditionally relied on identifying the size of the discrepancy between reading attainment as predicted on the basis of age and IQ scores and the actual level of attainment observed. Though criticised because of the doubtful predictive value of IQ for literacy attainment, such a formula permits the identification of children with disproportionate reading difficulty across a wide range of levels of intelligence, including those whose intelligence is below the average.

The disorder is now increasingly recognised among those engaged in education, and specialist courses designed to upgrade the knowledge and expertise of teachers are slowly being established. However, the problems not uncommonly persist into adult life as a continuing source of handicap and social embarrassment. With effort and specialist teaching some affected individuals appear to overcome their reading problems, proceeding successfully to higher education, though poor spelling usually persists as an aftermath.

Different theories abound as to the basis of the condition. Genetic influences are quite strongly apparent from twin studies and more recent molecular genetic studies in which loci on chromosomes 6 and 18 have shown strong and replicable effects on reading abilities (Francks *et al.* 2002). Environmental influences such as poor family circumstances or inadequate schooling clearly also make a contribution.

Traditionally, the disorder has been viewed by neurologists as 'maturationally' in nature, perhaps resulting from delayed myelination or other problems in crucial neural systems. However, recent studies have given support to the proposition that definable abnormalities of cerebral structure or function may sometimes persist even in adults who have largely compensated for their early deficits. These abnormalities include anomalous asymmetry, areas of architectonic dysplasia, disruption of the normal laminar organisation of the cortex, along with neuronal 'ectopias' consisting of abnormal nests of cells in the cortex and subjacent white matter. There may be an association with epilepsy.

MRI studies have confirmed that an unusual degree of symmetry of the planum is significantly more common in dyslexic subjects than controls (Larsen *et al.* 1990). Moreover, in Larsen *et al.*'s study of 19 adolescent dyslexics, there was a close relationship between abnormal symmetry of the planum and measures of phonological dysfunction. Hynd and Hiemenz (1997) summarise more recent interesting findings concerning posterior perisylvian morphology in dyslexia. Other regional abnormalities affecting the splenium of the corpus callosum, which connects the regions of the angular gyri of the two hemispheres, have been noted as well as abnormal connections to the left fusiform gyrus, thought by some to represent a 'word form' area (see Demonet *et al.* 2004 for a review). Along different lines, Livingstone *et al.* (1991) and others have pursued the hypothesis that there are problems with relatively 'early' perception of visual material. Finally, Uta Frith and her colleagues have devised elegant strategies for exploring the role of defective phonological decoding in dyslexia, using PET to detect the brain regions involved (Paulesu *et al.* 1996). Problems in the domain of phonology are currently strongly favoured as a core problem in developmental dyslexia (Snowling 1996), and phonological strategies appear to be especially effective with many dyslexics in attempts at remediation. Moreover, among those dyslexics who attain academic

success, this is often largely achieved through acquiring a large 'sight vocabulary', and underlying deficits in phonology may persist throughout adulthood. An excellent review of the research in this area and its implications is provided by Vellutino *et al.* (2004).

Jargon aphasia

'Jargon aphasia' is the term used when speech is produced freely, volubly and clearly, but with such semantic jumble and misuse of words that meaning cannot be discerned. Typically there are phonetic distortions, neologisms, words put together in meaningless sequence, and sequences which are entirely irrelevant. The intonation and rhythm of formal speech are nevertheless preserved. Jargon aphasia is conventionally regarded as representing a severe example of primary sensory aphasia, perhaps with superadded difficulties due to pure word-deafness, or perhaps with a marked degree of generalised intellectual impairment. Kertesz and Benson (1970) have reported typical severe neologistic jargon in patients with both Wernicke's and conduction aphasia.

Weinstein *et al.* (1966) were led to conclude quite differently that jargon aphasia represents aphasia in conjunction with anosognosia, rather than a distinctive pattern of breakdown in the intrinsic speech structure. In their patients receptive difficulties were rarely severe, and the distinctive accompanying feature was disturbance of consciousness sufficient to produce confabulation, disorientation and reduplicative delusions. In conformity with their observations on anosognosia generally (see Anosognosia, later), the jargon often appeared selectively when the patient was questioned about his disabilities, and more coherent speech was produced in relation to neutral topics. The pathological basis was a lesion of the dominant hemisphere along with additional brain damage elsewhere, and all patients had bilateral cerebral involvement. However, in favour of the conventional view that jargon represents a primary receptive defect, with failure to monitor speech productions, is the finding that patients who display it are not disturbed in the normal fashion when made to listen to delayed auditory feedback of their own speech productions.

Psychiatric disturbance and aphasia

Benson and Geschwind (1971) and Benson (1973) summarise the common forms of reaction that may be seen in aphasic patients. These differ considerably in the different forms of language defect.

In primary motor aphasia (Broca's aphasia), frustration and depression are frequently seen, or more rarely the 'catastrophic reaction' in which tension and embarrassment culminate in a sudden outburst of weeping or anger with the patient's realisation of his failings. Indeed the absence of distress among such patients is usually indicative of widespread cerebral damage and consequent impairment of general intellectual ability. Both frustration and depression are con-

sidered to indicate a more favourable prognosis for recovery with therapy, representing as they do an awareness of the speech difficulties. On the other hand, angry negativism with hostile responses and refusal to participate in treatment can sometimes emerge and seriously complicate rehabilitation.

In contrast, the patient with primary sensory (Wernicke's) aphasia typically shows a lack of interest in, or even unawareness of, his language problems. Such patients often act as though they believe their own speech to be normal and as though they feel that people around them fail to speak normally. Agitation and sometimes severe paranoid reactions may ensue, with suspicions that others are talking about them, plotting against them or deliberately using unintelligible jargon to prevent them from understanding. Outbursts of impulsive aggressive behaviour may be seen. In Benson's experience almost every patient who had needed custodial care during recovery from aphasia had suffered a paranoid reaction secondary to severe comprehension disability. Aphasia is frequently followed by calamitous alterations in lifestyle and economic status, along with disruption of simple pleasures such as conversation, reading or watching television. Social and family status are often undermined, irrespective of the presence of other handicaps such as hemiparesis, likewise confidence in sexual functioning.

Language and schizophrenia: the problem of 'thought disorder'

Thought disorder is the label that psychiatrists use to describe what is essentially an expressive disorder of spoken language, found in schizophrenia but not exclusive to that disorder. The distinction between the language disorder seen in certain schizophrenic and manic patients and the phenomena of aphasia due to brain damage needs to be very carefully distinguished. This can only be done by careful attention to the *form* of language output and by comprehensive tests of language function. Linguists who have studied schizophrenic speech have reached different conclusions, some arguing for a distinct disorder of language and others that such speech can be classified within the standard aphasia rubric. In one study that used speech transcripts from patients with schizophrenic thought disorder and (mostly) fluent aphasias, clinicians were poor at distinguishing the two (Faber *et al.* 1983). The 'word salad' of the chronically deteriorated schizophrenic may sometimes closely resemble aphasic speech; conversely, some patients with aphasia are mistakenly diagnosed as psychotic for long periods of time, especially those with primary sensory aphasia or transcortical sensory aphasia who produce a wealth of paraphasic neologisms. The neurological examination is often negative in such patients, their output is vague and apparently 'confused', and they may react negatively to the examiner's speech in a manner suggestive of psychosis. Any sudden onset of speech disorder must therefore always dictate

caution, even in the established chronic schizophrenic patient.

Gerson *et al.* (1977) analysed tape-recorded interviews with groups of posterior aphasic and schizophrenic patients in order to determine the features most useful in making the clinical distinction. The length of verbal responses to open-ended questions was considerably shorter among the aphasics, and these did not show the bizarre reiterative themes frequently encountered among the schizophrenics. The aphasic patients showed at least some awareness of their language difficulties, and used gestures or pauses to enlist the examiner's aid, whereas the schizophrenic patients were impervious to the adequacy or otherwise of their communication. Vagueness of response arose from word-finding difficulties in the aphasic patients but was apparently attributable to shifts of attention in the schizophrenics. The 'circumlocution' of aphasia could thus often be contrasted with the 'circumstantiality' of schizophrenic speech. In Faber *et al.*'s (1983) study, paraphasias were equally distributed among the two patients groups but frank incoherence, idiosyncratic use of words and tangentiality were more common in the thought disorder group.

In a recent and fine-grained application of an aphasiological approach to schizophrenic thought disorder, Oh *et al.* (2002) compared a carefully selected group of six patients with thought disorder and a matched comparison group of seven patients without. They used a battery of tests including the Boston Diagnostic Aphasia Examination (BDAE) coupled with a quantitative analysis of patients' utterances, and in a subgroup the Psycholinguistic Assessment of Language Processing in Aphasia (PALPA) and the Test for the Reception of Grammar (TROG). They found that some of the abnormalities observed in the speech of patients with schizophrenia, including syntactic errors, may be accounted for by their general cognitive impairment. This implies that deficits in attention and concentration or working memory are at the root of such problems and that higher-level problems of discourse planning reflect problems with planning generally. Of particular interest was the finding that the thought-disordered group, even those with preserved cognitive functioning, showed most impairment at the level of semantics in their expressive speech. This was in contrast to high levels of visual confrontation naming and ability to comprehend complex material, for example '... working the mind can comfort the bathroot as well, so it can be growthful, understand?' elicited during conversation. Attempts to recount fairy tales elicited disorganised and tangential speech that lacked a global semantic structure, presumably because of the open-ended, unconstrained nature of these tasks. Putting all the results together the authors characterised 'schizophasia' as an expressive semantic abnormality with preserved naming. In line with the main locus of impairment as being at the semantic level, Rodriguez-Ferrera *et al.* (2001) also found ample evidence of semantic disorders in speech in their

sample of 40 schizophrenia patients using the Pyramid and Palm Trees test, in which the subject is shown the written name of an object (e.g. an Egyptian pyramid) and then has to decide which of two other words is related to it, a palm tree or a pine tree. The thought-disordered patients' errors on this task revealed impairments at the level of semantic representations or concepts. This supported work by Kuperberg *et al.* (1998, 2000) which showed that thought-disordered patients (in comparison to non-thought-disordered controls) were less 'surprised' by linguistically anomalous endings to spoken sentences, indexed by relatively less prolongation in reaction time to press a button indicating they had heard a target word at the end of the sentence. They were less sensitive to linguistic (syntactic, semantic and pragmatic) violations because they were apparently unable to use linguistic context to form an overall semantic representation needed to process speech online.

Reduced expression

Poverty of speech and poverty of thought content are cardinal symptoms of schizophrenia normally assessed through the patient's spoken output. Reduced or slowed speech may reflect depressed mood and psychomotor retardation generally, as well as part of the negative schizophrenia syndrome. Non-fluency in this situation may occasionally need to be distinguished from a Broca's aphasia. Interestingly, reduced left prefrontal activation as measured by PET may accompany such deficits in both schizophrenia and depression (Dolan *et al.* 1994). Parkinsonism, either idiopathic or secondary to antipsychotic medication, may cause a similar clinical picture. Again, one might argue whether poverty of speech is truly a language disorder or a higher-level problem of initiation and planning. 'Dynamic aphasia' is the term sometimes given to the rare neurological syndrome in which spontaneous verbal output is much reduced but is normal when 'unlocked' by presentation of a picture or a simple question or a repetition task. It is initiation of speech that is compromised due to a left frontal lesion, perhaps localised to Brodmann's area 45.

The verbal fluency test may be used to quantify reduced speech in terms of a psychometric deficit. The patient can be asked to generate as many words as possible in a minute beginning with a given letter (F, A or S). This can be contrasted with semantic fluency in which the patient is asked to produce as many words as possible from a given category (e.g. four-legged animals). Generally, more items are produced in the latter situation, but where the semantic system is compromised (in Alzheimer's disease and, some would argue, schizophrenia) the pattern may be reversed.

Conversion disorders

It is only on rare occasions that difficulty arises in distinguishing between psychogenic and organic disturbances of language function. The most common hysterical speech

disorder consists of complete aphonia or mutism, or if sounds are produced there are usually no recognisable words at all but repetitions of phonemes and babble reminiscent of 'speaking in tongues' found in some evangelical religious settings during trance. A very rare example of dyslexia and dysgraphia of psychogenic origin has been described by Master and Lishman (1984).

Executive (frontal lobe) syndromes

Certain clinical features have long been associated with damage to the frontal lobes. These are not unique to frontal lobe pathology, but they are seen more regularly and perhaps more strikingly than after damage to other cortical structures. This lack of one-to-one correspondence between behaviour and lesion location led Baddeley and Wilson (1986) to coin the term 'executive dysfunction' for what had previously been known as 'frontal lobe dysfunction'.

Clinical picture

Evidence about this syndrome has come from studies of patients with various types of brain pathology. These include patients with head injury or frontal lobe tumours. Evidence has also accumulated from studies of patients after surgical excisions of frontal lobe lesions and, in the past, from patients who had extensive frontal leucotomies. The consensus of evidence suggests that lesions of the convex lateral surface (dorsolateral cortex) are especially prone to mental slowing and a lack of spontaneity, whereas lesions to the orbital undersurface of the brain (ventromedial pathology) are liable to have adverse effects on personality and social behaviour. Bifrontal lesions appear particularly damaging. The most striking changes are often in terms of behaviour, social awareness, habitual mood, volition, and psychomotor activities.

Commonly, there are what might be described as 'negative' symptoms. These include a lack of initiative and spontaneity, usually coupled with a general diminution of motor activity. Responses are sluggish, tasks are left unfinished, and new initiatives rarely undertaken. In consequence, the capacity to function independently in daily life can be profoundly affected. Yet when vigorously urged, or constrained by a structured situation, the patient may function quite well. Hebb (1949) described how cognition and intellect can be apparently unaffected despite huge frontal lesions, and the patient may achieve virtually normal performance in situations in which the examiner provides the impetus, such as in many formal tests of intelligence. How far the impairment of initiative represents a true loss of interest, or an apparent loss due to impaired volition, is often hard to discern, but this apathy and inertia may closely mimic depression.

Other patients tend to show 'positive' symptoms. They are restless and hyperactive rather than sluggish, but again are

likely to display a lack of purposive goal-directed behaviour. Their mood is often mildly euphoric and out of keeping with their situation. There may be rather empty high spirits, accompanied by a boisterous over-familiarity in manner. Such changes are rarely sustained, however, and when left to themselves these patients become inert and apathetic. Outbursts of irritability are also common and a childlike petulance may also be seen. The euphoria is sometimes elaborated into a tendency to joke or pun, to make facetious remarks or to indulge in pranks. Very occasionally, it extends to a state of excitement, pressure of speech, and ebullience, which can be termed 'secondary mania'.

Serious changes are observed in social awareness and behaviour. Typically, the patient is less concerned with the consequences of his acts than formerly. Loss of 'finer feelings' and social graces form part of a general coarsening of the personality. In interpersonal relationships, there is a lack of the normal adult tact and restraints, and a diminished appreciation of the impact of behaviour on others. Judgement may be markedly impaired. The patient shows little concern about his future and fails to plan ahead or to carry through ideas. Inability to forejudge the consequence of actions leads to foolish or irresponsible behaviour. Normal social restraints fail to exert control. Disinhibition is sometimes apparent in sexual behaviour, and may vary from lewd remarks to overt disinhibited behaviour that may even precipitate criminal charges.

These changes are seen to varying degree, sometimes merely as a blunting of the previous personality, but sometimes as a radical change of behaviour that is grossly disabling. The patient usually has little insight into the changes which have occurred. The component symptoms may be seen in different combinations, but there is a certain commonality from one patient to another, which has led to the continuing use of the terms 'dysexecutive' or 'frontal lobe' syndrome.

Classical case reports

Harlow (1868 [1993]) described the case of Phineas Gage, a railway engineer in New England. Gage's job was to bore a hole, lay explosive, cover it with sand, and then to use a fuse and a tamping iron to set off the explosive. However, on one occasion, he made a grave mistake, placing the tamping iron directly over the explosive, at which point there was an explosion that sent the iron through his skull and for a further 20 feet or so into the air. Remarkably, Gage did not lose consciousness, and he was able to walk to the cart which took him to hospital. In fact, he lived for another 20 years. He had little difficulty with language or memory, and his motor skills were unchanged. However, there was a pronounced change in personality and behaviour: whereas he had been considered an outstanding employee, he became unreliable, disrespectful and was lacking in social skills, and soon lost

his job. Harlow (1868) attributed this altered behaviour to damage to the frontal lobes of Gage's brain. Gage's body was exhumed in 1866, and the skull and the offending tamping iron were preserved in a Harvard museum. This allowed Damasio *et al.* (1994) to carry out modern neuroimaging on the skull and to estimate the precise location of Gage's brain lesion. They concluded that his lesion would have principally involved the orbitofrontal and anterior medial frontal regions bilaterally.

Eslinger and Damasio (1985) described a somewhat similar patient. This man was chief accountant, a college graduate, who had been extremely successful in his early career, rapidly climbing his professional hierarchy. A large frontal meningioma was removed surgically, involving a large portion of the orbitofrontal cortex but also involving dorsolateral frontal cortex. Although his IQ and memory were well preserved, this man's professional life deteriorated strikingly. He set up business with a former coworker, but the business failed and he became bankrupt. He drifted through several jobs, but he was found to be disorganised and was dismissed from each of them. He would take two hours to get ready in the mornings; he was somewhat obsessive, and indecisive. Purchasing goods required lengthy consideration of brands, prices and methods of purchase.

Interestingly, Shimamura (2002) has described similar phenomena in the photographer Eadweard Muybridge. Muybridge, who was born in Kingston upon Thames, emigrated to North America as a young man, finding his way to California. However, he was caught up in a stagecoach robbery, in which he was thrown from the stagecoach injuring his head. Subsequently, Muybridge returned temporarily to the UK, where he was looked after by Sir William Gull of Guy's and St Thomas's hospitals during his convalescence. He returned to North America, and most of his photographic inventions and innovations, including his famous studies of people or racehorses in motion (which were the precursor of cine-photography), were carried out during the next 30 years. However, his behaviour was changed in ways which Shimamura (2002) attributes to frontal lobe damage as a result of the head injury. During this period, Muybridge shot dead his wife's lover but managed to obtain an acquittal on the grounds of his brain injury.

A more specific deficit was described by Lhermitte (1986), who reported imitation and so-called 'utilisation behaviour' in patients with frontal lobe lesions. Lhermitte observed patients in complex everyday life situations, i.e. without the constraints normally imposed during clinical assessment. He noted behaviours which he proposed reflected a lack of personal autonomy, coupled with an excessive dependence on the social and physical environment ('environmental dependency syndrome'). Decisions concerning the patients' actions were not made for themselves, but the behaviours were called forth by surrounding external stimuli: 'For the

patient, the social and physical environments issue the order to use them, even though the patient "himself" or "herself" has neither the idea nor the intention to do so.' Lhermitte suggested that a shift in the balance between personal autonomy and environmental influences reflected decreased control by frontal systems over the parietal sensorimotor systems linking the individual to the world around. From this might follow such classic features as disinhibited behaviour, distractibility, loss of flexibility of action, and loss of self-criticism.

Thus when taken into a room containing a buffet, Lhermitte's patient laid out the glasses and offered him food, spontaneously behaving like a hostess. Confronted with make-up, she used it immediately, and seeing wool and knitting needles began to knit. Another patient, when taken into a bedroom with the sheet turned back, got undressed, went to bed and prepared to go to sleep. On hearing the word 'museum' while in an apartment, he began methodically to examine the paintings on the wall, and walked from room to room inspecting various objects.

Neuropsychology of executive function

An enormous range of cognitive functions has been attributed to the frontal lobes. These include the initiation of responses, the maintenance of responses, the suppression of irrelevant or inappropriate responses, the planning and organisation of behaviour, abstract and conceptual thinking, monitoring and editing of responses, the temporal organisation of behaviour and memory, aspects of working memory, and the encoding and/or retrieval of new or remote episodic memories.

Consistent with this, a wide range of tests has been developed that purport to measure some aspect of executive function. Commonly employed are FAS verbal fluency, the Wisconsin or Modified card-sorting tests, cognitive estimates, Trailmaking, various tasks that require alternating patterns of behaviour or shifts in response, the Stroop test, working memory or continuous performance tests, prospective memory, and source or temporal context memory tasks. One view is that the commonality in such tests boils down to a single factor, akin to Spearman's 'g' (Duncan 1986, 2001), which guides activation of representations stored elsewhere in the brain. The alternative view is that, to varying degrees, these tasks reflect differing aspects of frontal lobe functioning. In practice, correlations between performance on these different tasks are relatively low, especially when IQ has been partialled out (Shoqeirat *et al.* 1990; Kopelman 1991). Moreover, patients with large frontal lesions can show significant behavioural impairments without this necessarily being reflected in their performance on any of these tests (Shallice & Burgess 1991a,b). More recently, 'ecologically valid' virtual reality tasks have been developed (Morris *et al.* 2005), but questions still arise as to how and to what degree

these relate to the more traditional tasks, and whether frontal lobe function should be conceived as having an underlying unity or whether it is essentially fragmented.

In the light of this, attempts have been made to 'model' frontal lobe function. Wood and Grafman (2003) have reviewed some of these theories. These authors point out that the ventromedial prefrontal cortex has reciprocal connections with brain regions associated with emotional processing (amygdala), memory (hippocampus) and higher-order sensory processing (temporal visual association areas), as well as with dorsolateral prefrontal cortex. The dorsolateral prefrontal cortex has reciprocal connections with brain regions associated with motor control (basal ganglia, premotor cortex, supplementary motor area), performance monitoring (cingulate cortex) and higher-order sensory processing (association areas, parietal cortex). The ventromedial prefrontal cortex is therefore well suited to support functions involving the integration of information about emotion, memory and environmental stimuli, and the dorsolateral prefrontal cortex to support the regulation of behaviour and control of responses to environmental stimuli.

Perhaps the most popular model of executive or frontal lobe function is the *supervisory attentional system* model of Norman and Shallice (1980; see Shallice 1988). This model was based on two main premises: the first that the routine selection of routine operations is decentralised, and the second that non-routine selection is qualitatively different and involves a general-purpose supervisory system, which modulates rather than dictates the operation of the rest of the system. The model postulates that routine mental procedures are handled using processing modules, schemata linking these modules together for a particular task, and 'contention scheduling' which allows multiple routine tasks to occur together in an efficient way. For non-routine activities, the supervisory system was required to control the schemata and contention scheduling. A criticism of this model (and also of Baddeley's 'central executive' working memory model) is that it is essentially homuncular. However, more recently, an elaboration of this model has been proposed, which postulates at least six component processes that are recruited by the supervisory system in anticipation of, or early in, task performance (Stuss *et al.* 2005). These processes are energising schemata, task-setting, inhibiting task-irrelevant schemata, adjusting contention scheduling so that the automatic processes can work more smoothly, monitoring the level of activity in schemata, and controlling the 'if this, then that' logic required to move through the steps of a task. It is argued that these different higher-order processes, subcomponents within the unitary system, will allow the frontal lobes to perform a variety of 'anterior attentional' tasks, including focused attention, divided attention, sustained attention, inhibitory processes, switching attention, preparation in response to a signal, and setting an appropriate sequence of processes. Moreover, by

careful architectonic localisation of brain lesions, Stuss *et al.* (2005) have begun to examine the critical sites for performance of these tasks, arguing that the energisation of schemata is sensitive to pathology in the medial superior frontal regions, whereas the monitoring of stimulus occurrence and response behaviour is sensitive to right lateral frontal pathology.

Recent work has also examined the functioning of the frontal poles or anterior prefrontal cortices (Burgess *et al.* 2005). This region can be activated in functional imaging studies independently of other frontal lobe regions and, again, lesions to this region do not necessarily result in impaired functioning on traditional executive tests. Most commonly, impairments are seen on tests involving multi-tasking or prospective memory. Burgess *et al.* (2005) have postulated that this region is particularly involved as a 'gateway mechanism' that controls switching between stimulus-orientated and stimulus-independent thought (compare Lhermitte, above). This cognitive control mechanism is used in a wide range of situations critical to competent behaviour in everyday life, ranging from straightforward 'watchfulness' to complex activities such as remembering to carry out intended actions after a delay, multi-tasking, and aspects of recollection. These are situations which require the person to be particularly alert to the environment, to concentrate deliberately on his thoughts, or to be involved in conscious switching between these states. The authors have speculated that damage to the functioning of this region might be relevant to psychiatric phenomena such as hallucinations and intrusive thoughts.

Other theories of frontal lobe functioning have been well reviewed by Wood and Grafman (2003); more specifically, the putative role of ventromedial frontal lesions in the genesis of spontaneous confabulation has been noted above. Neuropsychological research on executive functioning also has practical clinical implications in terms of the development of cognitive and behavioural rehabilitation strategies (e.g. goal management training; Levine *et al.* 2000) and in terms of examining the interaction with behavioural genetics, using contemporary techniques to identify genetic markers (e.g. O'Keefe *et al.* 2004).

Disorders of action and the apraxias

Apraxia refers, in essence, to an inability to carry out learned voluntary movements, or movement complexes, when this cannot be accounted for in terms of weakness, incoordination, sensory loss or involuntary movements. The patient cannot willingly set the movement in train or guide a series of consecutive movements in their correct spatial and temporal sequence, even though the same muscles can be used and analogous movements performed in other contexts.

Liepmann (1905) first established the validity of apraxia as a clinical entity in its own right, and that both unilateral and

bilateral forms of the syndrome could occur. He showed that it could be differentiated from language disorders and paralysis, although he argued that apraxia was not a simple unitary disorder but that it could arise at a number of stages in the processes involved in organising a voluntary action. Geschwind and Damasio (1985) pointed out that apraxia is often overlooked on clinical examination since it is unlikely to be complained of by the patient or his family. The patient who is apraxic on testing will usually perform learned movements normally in a natural setting, and especially when he can see and manipulate objects in their proper environment. In consequence, the disorder is probably a good deal commoner than is usually appreciated.

The essential nature of apraxic disturbances is still poorly understood. Aphasia is an accompanying defect in the great majority of cases and deficient comprehension of commands may sometimes play a part. Agnosia for an object may hinder the patient from carrying out purposive movements appropriate to its use, while agnosia for spatial relationships will similarly interfere with the copying of a movement by imitation. Over and above such complications, however, there is usually a higher-order cognitive impairment with a specific bearing on motor function.

The difficulties for any explanatory system include the observation that movements which cannot be performed to command can sometimes be performed in imitation of the examiner, or a movement which cannot be initiated is performed a moment later when the patient's attention is not directed towards it. Sometimes simple discrete movements are affected, and sometimes complex coordinated sequences as in the use of a tool. Frequently, performance is much better in the actual presence of the tool than when the patient is asked to demonstrate its use in imagination. To a surprising degree, whole-body movements to command are often found to be perfectly preserved, while limb and facial movements are defective. Hence, simple hierarchies of difficulty do not provide an adequate explanation for these anomalies.

Apraxia is probably more often seen in diffuse than in strictly focal brain lesions so that other intellectual processes are often involved. With focal lesions, however, other cognitive processes may prove to be largely intact, even though at first sight the severely apraxic patient is sometimes misdiagnosed as having a dementia. Nevertheless, such patients are severely handicapped in many tasks requiring the demonstration of intelligence. It is likely that the schemata for purposive movement are so interwoven in cognitive processes that their disruption is bound to have a more general adverse effect.

Brain (1965) suggested that purposive movements are organised by 'schemata' that may or may not enter consciousness depending on the context of the movement. The more practised the act, and the more automatic it has become, the more it will be carried out without conscious awareness

and conscious volition. Apraxia may be regarded as the result of disorganisation in such schemata and as taking place at various levels of complexity. At the highest level will be found disturbance where schemata are involved in the formulation of the idea of a movement; at the lowest, the schema consists of a motor pattern that regulates the selection of appropriate muscles. In contrast, Geschwind (1965) characteristically put forward a disconnection model, in which he postulated that lesions which disrupted connections between auditory association cortex and motor association cortex of the dominant hemisphere would result in an inability to carry out motor commands with the limbs on either side of the body. Lesions of the left motor cortex would produce a right hemiplegia together with apraxia limited to the left arm when the origin of the transcallosal pathway had been destroyed. Lesions of the corpus callosum would result in apraxia to command without dysphasia, and limited to the left arm and leg, since the motor cortex of the right hemisphere would now be isolated from the speech mechanisms of the left. More contemporary theories are discussed below.

Many varieties of apraxia have been postulated and these are briefly outlined below.

Limb kinetic apraxia: the skill and delicacy of movements is disturbed for both complex and simple actions. Thus the patient may have difficulty in doing up buttons or opening a safety pin. The difficulty the patient experiences reflects the degree of muscular complexity, rather than the psychomotor processes involved. It may be confined to particular muscle groups, and even to certain fingers of the hand. This form has characteristics intermediate between a paresis and apraxia, and therefore is often excluded from the apraxias proper. It results from a relatively small lesion of the contralateral premotor cortex.

Ideomotor apraxia refers to the inability to carry out a requested movement properly. It may be regarded as a disturbance of voluntary movement at a fairly low level of motor organisation or, alternatively, as a disturbance of the use of space centred on the body. The patient can often formulate to himself the idea of a movement that he wishes to perform but is unable to execute it. Thus the voluntary impulse does not evoke the appropriate organisation of the movement in space and time. For example, the patient cannot raise his hand or wave it to command, even though the instructions are understood. In some cases, he could copy a couple of movements, but this too may fail. Yet essentially the same movements can be performed automatically, as in signalling goodbye or in the course of other activities to which his attention is not directed. The disorder is usually bilateral and most commonly involves the arms. Unilateral apraxia almost always involves the left arm, and then is typically seen with right hemiplegia and aphasia.

Ideational apraxia: the patient is unable to carry out coordinated sequences of actions, such as taking a match from a box and striking it, or to perform the complex movements involved in using such tools as a comb or pair of scissors. Ideomotor apraxia may coexist or, in contrast, the patient may be capable of straightforward imitation of simple movements. Sometimes, performance is clearly better when the tool is held by the patient than when he attempts to demonstrate the action in the abstract. Variability may be seen from one task to another and on different occasions. In ideational apraxia, the conception of the required movements appears to be disturbed, together with planning of the acts to be accomplished. It may be regarded as a form of 'programming' apraxia, whereas ideomotor apraxia is a more basic executory defect. Ideational apraxia is always bilateral. If based on circumscribed pathology, the lesion usually involves the dominant hemisphere, usually in the parietal or temporal lobes. It is most commonly seen in diffuse brain lesions, usually accompanied by severe dysphasia or a considerable degree of generalised cognitive impairment.

Apraxia for dressing refers specifically to difficulty in putting on clothes. The patient cannot relate the spatial form of garments to that of his body, putting a jacket on back to front or the arm in the wrong sleeve. Buttons and laces present particular difficulties and are often left undone. The concept of dressing apraxia is useful clinically in drawing attention to a dramatic symptom when more refined tests of apraxia and agnosia have yet to be performed. However, it is improbable that it reflects a distinct form of apraxia, and the symptoms probably depend on a variety of deficits that differ from case to case. In many cases, right-left disorientation, unilateral inattention, neglect of the left limbs and other disturbances of body image are likely to contribute. The disorder is often seen in dementia, and more commonly in bilateral or right-sided parieto-occipital lesions than left-sided lesions.

Constructional apraxia refers to instances where the spatial disposition of actions is altered without any apraxia for individual movements. This becomes apparent in tasks involving the use or representation of space, e.g. in the constructional copying of patterns under visual control. The defect is clearly not purely motor in nature, but involves perceptual functions as well. This may be immediately apparent in the patient's satisfaction with a grossly imperfect copy of presented test material. Many authorities have interpreted constructional apraxia as a form of visuospatial agnosia.

The neuropsychology of action

McCarthy and Warrington (1990) argued that the classificatory systems for apraxia are confusing and inconsistent. They advocated a strictly empirical task-oriented framework rather than one based on particular theoretical perspectives.

They considered disorders of voluntary action in terms of the following.

1 Disorders of simple repetitive movements, involving either unimanual or bimanual coordination of repetitive movements. Unimanual movements can be damaged by lesions in either hemisphere, whereas bimanual coordination problems usually follow damage to the frontal lobes or the supplementary motor region.

2 Disorders of unfamiliar actions and action sequences can involve single hand positions, usually affected by damage to the left parietal lobe, whereas copying or executing unfamiliar action sequences can be affected by lesions in either the left frontal or the left parietal lobes.

3 Impairment can occur in the ability to carry out familiar gestures, such as saluting or waving goodbye. Impairment in producing meaningful gestures on command has consistently been shown to result from left parietal lesions.

4 Impairments can be seen in producing actions appropriate to objects or in patients' ability to mimic the use of a single or multiple objects. Such impairments result from left hemisphere damage, and it appears that regions around the parieto-temporal junction are most likely to be implicated.

5 Body-part specific actions can be affected, as in gait apraxia (difficulty walking) or oral apraxia, in which the patient may be unable to protrude the tongue, open the mouth or cough on command, although these gestures do occur spontaneously, for example when eating. Gait apraxia is associated with bilateral frontal lesions, and oral apraxia with highly specific lesions in the left central operculum and insula.

6 Constructional apraxia can involve either left-sided or right-sided lesions, but different patterns are observed. Left hemisphere lesions give rise to oversimplified drawings, whereas right hemisphere pathology results in distortions in the spatial arrangements between the parts or in hemispatial neglect.

An influential distinction, much cited in neuropsychological discussions of apraxia, was made by Milner and Goodale (1992). They reported the case of an agnostic patient (D.F.) who had a profound deficit in judgements of visual form, including the orientation of bars, yet was able to match the position of her hand successfully to post an object through a slit that was presented in a range of orientations. In other words, D.F. could not access visual information for perceptual analysis (in an experimental psychophysical task) but could nevertheless use perceptions in the control of action. This led to the postulation of two visual perceptual pathways: a 'ventral' stream, terminating in the temporal lobes, which was concerned with object representation and recognition (of 'what' was out there), and a more pragmatic 'dorsal' stream, terminating in the parietal cortex, which was concerned with describing the visual world for the purposes of acting upon it ('where'). Sometimes these pathways are conceived as being involved in vision-for-perception

(semantic) and vision-for-action (pragmatic), respectively. This model has been criticised for not saying much about the control of action *per se* and the internal generation of willed action (Haggard 2001), and for underestimating the role of the parietal lobe in, on the one hand, allowing the perception of spatial relations among objects and, on the other, storing complex representations of actions in the form of schemata (Jeannerod & Jacob 2005). It also fails to take account of the different levels of awareness which may occur in motor performance (Johnson & Haggard 2005). Interestingly, recent functional imaging studies, reviewed by Blake-moore and Frith (2005), have found that observing, imagining or in any way representing an action excites the same motor programmes used to execute that action; in humans, a proportion of the brain regions involved in executing actions are activated by the mere observation of the action (known as the 'mirror system'). A specific but particularly interesting topic of investigation involves functional imaging studies of differing aspects of musical performance (Parsons *et al.* 2005).

Chainay and Humphreys (2002) have attempted to integrate many of the observed clinical and neuropsychological phenomena into what they call a 'convergent route model for action'. They suggest that perceptual information interacts directly with semantic information in selecting the appropriate action to make to an object. Semantic input defines the appropriate category of action, whilst the direct perceptual input helps to determine the optimal parameters for the motor programme (e.g. the appropriate grip and plane of action). These authors argue further that actions are contingent on a network of cortical, and possibly also subcortical, structures that are recruited according to the modality of input. Tactile input may facilitate object use through a pragmatic dorsal cortical pathway, whereas a semantic route to action is contingent on activation of 'action semantics' involving left frontal and left parietal regions. The authors described two patients whose problem seemed to be in selecting actions within an action output lexicon; these patients both showed generally good object recognition and naming, but were impaired in discriminating whether objects were correctly used. The authors suggest that these two patients were impaired at retrieving from an 'action output lexicon' information about how objects should be used. A third patient had a central deficit in accessing semantic knowledge about objects. This deficit was generally consistent across items, and it arose irrespective of the modality in which objects were presented (e.g. visually or tactilely) and irrespective of the task (naming, gesturing) if access to semantic knowledge was required. Elsewhere, Humphreys (2001) has argued that there can be a 'direct route' to action from perceptual input, even where semantic knowledge of objects and their use is severely damaged. The convergent route model of action postulates converging and interacting routes to the execution of motor programmes.

Disorders of perception and the agnosias

The term 'agnosia' was introduced by Freud (1891), although the condition had been described much earlier than this. It may be defined as 'an impaired recognition of an object which is sensorially presented while at the same time the impairment cannot be reduced to sensory defects, mental deterioration, disorders of consciousness and attention, or to a non-familiarity with the object' (Frederiks 1969). Agnosia thus implies a disorder of perceptual recognition that takes place at a higher level than the processing of primary sensory information. Even though elementary sensory processes are themselves unimpaired, there is an inability to interpret sensory information, to recognise its significance and endow it with meaning on the basis of past experience. Lissauer (1890), on the basis of his early case, divided the process of recognition into two stages: first a stage of processing whereby elementary physical stimuli are integrated to form a conscious percept ('apperception'), then the stage of associating the percept with other notions such as memory traces which endow it with meaning ('association'). Thus distinct forms of apperceptive and associative agnosia have come to be recognised.

Clinically, the situation is identified when there is a failure of recognition that cannot be attributed to a primary sensory defect or to generalised intellectual impairment. A patient may, for example, fail to recognise an object by sight and be unable to name it, demonstrate its use or relate it to a matching picture, even though vision is intact for other purposes. Nevertheless, the same object is readily recognised by means of touch, showing that the patient is suffering from a modality-specific defect of higher cerebral function and not from aphasia or apraxia. The several types of agnosia related to vision have received most attention, but agnosias are also described in relation to hearing and touch.

Brain (1965) pointed out that the underlying disorder of function must have something in common with both aphasia and apraxia, since a patient can only demonstrate that he recognises an object by using speech or action; in effect agnosia represents an isolated aphasia and apraxia related to a particular object when it is perceived through a particular sensory channel.

In the sections that follow the classic agnosic syndromes are described, and also the more common forms of related perceptual defect.

Visual agnosias and visual perceptual defects

Visual object agnosia

In visual object agnosia an object cannot be named by sight but is readily identified by other means such as touch or hearing. There is equally failure to select a matching picture from a group or to indicate the appropriate use of the object, showing that this is not a naming defect alone. Sometimes

the patient may describe a use appropriate to an incorrect recognition. The difficulty may vary from day to day, and sometimes an object may be recognised from other cues in its familiar surroundings but not elsewhere. Usually the problem is restricted to small objects, but in severe examples it may extend to larger objects, with consequent difficulty in finding the way about.

In general, the more complex the visual information, the more difficulty the patient experiences. Greater problems may be encountered with two-dimensional representations, such as line drawings or photographs, than with the actual objects themselves. Commonly, though not invariably, faces continue to be recognised. In many reported examples there has been difficulty in describing objects from memory and in drawing them (i.e. loss of visual images of objects), and also difficulty with colour recognition, dyslexia and dysgraphia.

In keeping with the distinction between apperceptive and associative forms of agnosia described earlier in this section, subdivisions have been attempted in the field of visual object agnosia (McCarthy and Warrington 1990, pp. 22–55). Patients with visual apperceptive agnosia are particularly sensitive to difficulties surrounding perceptual aspects of identification and fail when these are increased, for example when the perceptual characteristics of an object are partially obscured, or distorted by photographing it from unusual angles. In contrast, visual associative agnosics fail on tests where objects must be matched according to common functions as opposed to physical identity (e.g. a watch and a clock) or when asked to pick out clear pictures of objects that belong to a particular class (e.g. objects found in a kitchen). In this they betray a lack of recognition of the essential meaning of the objects. Interestingly, associative agnosia can sometimes appear to be category specific, with particular difficulty centring on animate or inanimate objects, pictorial representations of concrete or abstract items, or even categories as specific as animals or foods.

Apperceptive agnosics cannot copy objects or drawings unless they do so slavishly and very slowly, often producing frequent errors; associative agnosics can perhaps make reasonable drawings of objects even when they cannot identify them. A double dissociation can sometimes be shown between these two forms of deficit: on the one hand failure to organise a coherent percept, and on the other failure to endow an adequately organised percept with meaning. In many patients, however, the features of both apperceptive and associative agnosia occur together, suggesting that the two may form a continuum (Jankowiak & Albert 1994). Stringent exclusion of subtle deficits in vision and multiple scotomata, as may occur following carbon monoxide poisoning, is required before diagnosis of agnosia can be made.

Clear-cut cases of visual object agnosia are rare. Lesions in the posterior parts of the cerebral hemispheres, involving the occipital, parietal and posterior temporal regions, are almost invariably responsible. Warrington (1985) suggests that fol-

lowing basic sensory analysis, input to the right hemisphere achieves perceptual categorisation and input to the left hemisphere semantic (meaning) categorisation. Accordingly apperceptive agnosic deficits can occasionally be seen in unusually clear form with right hemisphere lesions and associative agnosia with left hemisphere lesions. However, Jankowiak and Albert's (1994) careful review makes it clear that bilateral pathology can be detected in the great majority of cases, even though PET activation studies suggest that object identification takes place predominantly in the left posterior hemisphere. Apperceptive agnosia tends to be associated with diffuse or multifocal lesions, whereas associative agnosia may occur with more focal pathology within the territories of the posterior cerebral arteries. It is noteworthy that the three cases of apperceptive agnosia studied by Grossman *et al.* (1996) showed bilateral occipitotemporal hypoperfusion on PET, even though the MRI appearances had been unremarkable in two. Finally, Riddoch and Humphreys (2003) review more recent work on the visual agnosias including their own detailed case studies which illustrate perhaps better than any other method the logic behind the different types of perceptual abnormalities and their fractionation.

Prosopagnosia

Inability to recognise familiar faces has been described as a distinct and separate defect, which may or may not be combined with visual object agnosia and is certainly much commoner than the latter (Hécaen & Angelergues 1962). In extreme form the patient cannot recognise his own face in a mirror (see below). Classically, the patient with prosopagnosia can readily identify others from their voices or from other cues including their gait. The defect has been reported to be commoner with right than with left hemisphere lesions but in most cases there is probably bilateral involvement (Walsh 1994). This was strongly supported by Damasio *et al.* (1982b) in their analysis of post-mortem and CT scan data; bilateral lesions of the central visual system, situated specifically in the medial occipitotemporal regions, proved to be crucial for the development of prosopagnosia. Functional neuroimaging has highlighted the fusiform gyrus (often referred to as the fusiform face area or FFA), part of the medial occipital junction, as the central hub for face identity processing while the superior temporal sulcus is implicated in such aspects as eye gaze and facial movements. Lesions to the fusiform and adjacent lingual gyrus, and sometimes more anteriorly in the temporal lobe, may cause prosopagnosia, even if unilateral, especially if right-sided (see Barton 2003 for review).

The precise nature of the defect remains uncertain, and it seems likely that prosopagnosia is not a unitary disorder. Warrington and James (1967) showed a distinction between impaired recognition of a previously well-known face, which depends on long-term storage of visual information, and

impaired recognition of a previously unknown face from short-term memory. The former tended to be associated with right temporal lesions and the latter with right parietal lesions. De Renzi *et al.* (1991) propose a division into 'apperceptive' forms, in which a disorder in processing shape information prevents a sufficiently clear representation of the face to activate memory for it, and 'associative' forms in which the memory itself is defective. In some instances, however, the condition must be regarded as a 'face-specific disorder', as in the interesting example reported by McNeil and Warrington (1993); here a patient with severe and persistent prosopagnosia for human faces was still able to identify individual members of his flock of sheep from pictures of their faces alone! Neurophysiological recording from the human right temporal lobe has confirmed that there are discrete populations of neurones that are related to the perception and comparison of faces (Ojemann *et al.* 1992). Developmental cases have been described, sometimes with developmental anomalies such as occipital microgyria but by no means always (Barton 2003). Perceptual distortions applied to faces are discussed below.

Facial affect perception

Perception of facial expressions of emotion may be dissociable from facial identity. There is some debate as to whether the right hemisphere is 'dominant' for such expressions or perhaps those of negative valence. Most evidence points to a general role for the right hemisphere in affect perception (Kucharska-Pietura *et al.* 2003). However, some remarkably specific deficits in the perception of expressions of fear (with intact perception of other expressions, both negative and positive) have been described due to lesions of the amygdala, especially when bilateral (Brierley *et al.* 2004). Adolphs *et al.* (1994) have reported the patient S.M. with Urbach–Weithe disease, which manifested as a specific degeneration of the amygdala. The patient has also been shown to lack the normal emotional enhancement of memory and to be more trusting of unfamiliar faces than expected. Evidence from these clinical cases converges on functional imaging research. For example, Morris *et al.* (1996) carried out PET scans whilst subjects viewed photographs of happy or fearful faces that varied systematically in the intensity of the emotional expressions. The neuronal response in the left amygdala was significantly greater to fearful as opposed to happy expressions, and it increased with increasing intensity of fearfulness and decreased with increasing intensity of happiness. Moreover, this emerged without a requirement for explicit processing of the facial expressions; the subjects were merely asked to judge whether each face was male or female. Related work has suggested that the amygdala may even respond to expressions of fear presented too quickly for conscious awareness.

Disgust is another 'basic' emotion that can be detected reliably from facial expression alone. A few cases of lack of

disgust recognition have been described and the lesions appears to be in the caudate nucleus and perhaps the insula (Calder *et al.* 2000), again corroborating functional imaging work (Phillips *et al.* 1997).

Facial expressions may convey a wealth of information, from simple emotional state to complex 'social' emotions such as embarrassment or sympathy. Patients with neuropsychiatric disorders such as traumatic brain injury or frontotemporal dementia may misinterpret or fail to recognise important cues from facial expressions, leading to inappropriate or insensitive behaviour. It has been argued that an acquired failure to perceive sadness or fear in another (i.e. signals of distress) could lead to psychopathic behaviour while failure to understand a person's expressions of anger may compromise safety (Blair *et al.* 1999). Similarly, a general insensitivity to facial affect may both reflect and lead to emotional blunting as seen in psychotic and mood disorders. People with autism and Asperger's syndrome may have grave difficulty in understanding the meanings conveyed in facial expressions. All these conditions may lead relatives and carers to describe a lack of empathy in those affected. The usual near-instantaneous perception of such expressions as a whole that we take for granted may not be available in such disorders, where the individual parts of the face seem equally salient and rather unconnected.

Self-face perception

Failure to recognise one's own face has been noted in people with severe prosopagnosia. However, the most common setting for this symptom is severe dementia, where perception of the entire visual world is degraded and combined with faulty reasoning and confusion. A few cases have been described in which impaired self-recognition, the so-called mirror sign, seemed to be out of proportion to other deficits (Phillips *et al.* 1996) and others where the viewer is convinced that an additional, usually inauthentic version of himself is captured when looking into the mirror (a type of reduplication with features of Capgras' delusion). Usually, though, such complaints indicate depersonalisation without concomitant intellectual or neurological dysfunction. On closer questioning, the essence of the complaint, while obviously provoked by gazing at the mirror, is that the individual is unsure of his identity and feels detached from it.

Colour agnosia

Patients with colour agnosia show defective appreciation of the differences between colours and fail to relate colours to objects correctly, even though their primary colour vision is intact as shown by normal performance on the Ishihara chart. Thus they have difficulty in sorting objects according to colour, ordering them in series or matching colours one with another. A dominant occipital lobe lesion is usually responsible and a right homonymous hemianopia is frequently present.

A closely associated though separable defect consists of 'colour anomia' in which the subject is unable to name colours or to point appropriately to named colours, in the absence of any impairment of colour sense. Thus he may use the word 'blue' when shown a picture of a banana, yet be capable of placing the correctly coloured chip next to it. Such problems may be unaccompanied by any other form of language difficulty, representing an unusually clear example of disruption of neural systems that mediate between specific concepts and their corresponding word forms (Damasio & Damasio 1992). The lesion in such cases appears to lie in the temporal segment of the left lingual gyrus.

In central 'achromatopsia' there is a more profound loss of colour sense, extending even to an inability to imagine colours. The concept of colour itself is abolished and the world around, though perceived normally in form and depth, is seen in shades of grey. Damage in such cases is situated in the occipital and subcalcarine portions of the lingual gyri bilaterally (Damasio & Damasio 1992).

Simultanagnosia

Classically the patient fails to recognise the meaning of a complex picture while details are correctly appreciated. However, this is not attributable to difficulty in forming meaningful concepts, since with auditory information there is prompt understanding. Moreover, if plenty of time is given, or every individual feature of the picture is pointed out, the patient ultimately comprehends the meaning. In a similar way, words cannot be read except by spelling out individual letters.

The key problem appears to be with the perception of more than a limited number of units or configurations at a time. Thus tachistoscopic studies have shown that such patients have normal thresholds for the perception of single shapes and letters, but greatly elevated thresholds when more than one stimulus is presented at a time.

Coslett and Saffran (1991), in a detailed analysis of a case, suggested that the fundamental difficulty lay in the integration between object identity and information concerning spatial location when multiple items of visual information needed to be processed. They point out that the processing of multiple targets in an array must be carried out serially beyond a certain level, with storage of both the products of identification and their positions as the 'spotlight on visual attention' moves from one location to another. The inability to maintain appropriate linkages during the process of visual search appeared to account for their patient's failure. Posterior lesions of the dominant lobe have been implicated in patients who display the complete syndrome.

Problems in fixating on an object or directing fixation to a part thereof in an array may be regarded as simultanagnosia but tend to be seen more as problems in visuospatial attention. The term 'Balint's syndrome' is applied to this situation where there are difficulties in voluntary shifts of gaze with

concomitant problems in reaching and pointing. Bilateral posterior occipitoparietal lesions are to blame.

Visuospatial defects

After cerebral lesions a number of defects of visuospatial perception may be demonstrated. However, it remains uncertain whether failure to reproduce simple models and drawings depends on dyspraxic difficulties or failure of visuospatial analysis, likewise how far inability to draw from memory may further depend on defective visual imagery. Classic visuospatial agnosia is indeed widely regarded as broadly synonymous with constructional apraxia, as discussed below. Nevertheless, certain syndromes of localising value can be recognised as follows.

Visuospatial agnosia

Visuospatial agnosia is identified by failure on tasks which demand explicit analysis of the spatial properties of a visual display. This is most readily tested by asking the patient to reproduce simple designs under visual control: the copying of drawings or the construction of patterns with bricks or sticks. The Block Design and Object Assembly subtests of the Wechsler Adult Intelligence Scale will most readily indicate minor degrees of such a defect.

Usually the patient has no difficulty in finding his way about, though an itinerary on a map cannot be indicated and towns cannot be correctly located. In the most severe examples a loss of topographical memory (see later in section) may be present as well. An interesting fact, often noted, is that patients with marked visuospatial defects rarely make specific complaints about them. Thus visuospatial agnosia easily eludes routine examination and special tests are needed for its detection.

Visuospatial agnosia may affect drawing ability. Drawings made by patients with left parietal lesions tend to be coherent but simplified versions of the model, with omission of details but relative preservation of spatial relationships. Performance is notably improved when the patient is provided with a model to copy. Frequently associated defects include aphasia, apraxia, or components of Gerstmann's syndrome (see next section) such as right-left disorientation. Patients with right parietal lesions produce more elaborate drawings, but made hastily and without care, and the result is typically scattered and fragmented. Disorientation on the page is marked, the left side of the page is relatively neglected, and the drawings are often asymmetrical and show gross disorganisation of spatial relationships. The presence of a model is of little extra help.

Some therefore prefer to retain the term 'constructional apraxia' when the disorder results from dominant hemisphere lesions, and 'visuospatial agnosia' when it is due to non-dominant lesions, although the distinctions between the two are by no means universally acknowledged.

Some evidence has come from studies of patients after section of the corpus callosum that upholds the greater

importance of the non-dominant hemisphere in tasks demanding visuospatial analysis. In brief, the left hand often out-performs the right on unimanual construction tasks. Again there is the difficulty in teasing apart constructional (praxic) difficulties from purely perceptual ones (Bogen & Gazzaniga 1965; LeDoux *et al.* 1977).

Visual disorientation

A further defect of visuospatial ability consists of difficulty in localising objects in space by vision alone. As a result the patient cannot point accurately to an object or estimate its distance. Such difficulty can occur in either half-field of vision alone, contralateral to the side of a lesion, or involve the whole visual field with bilateral lesions. When involving the whole field of vision the patient has difficulty in finding his way around objects or in learning the topography of a room.

Visual disorientation is usually seen in conjunction with impairment on more complex visuospatial tasks, and the lesions are situated posteriorly within the hemispheres. Warrington and colleagues have suggested that there may be areas within the occipital lobes that contribute to the absolute localisation in space of a single object, whereas the integration of several spatial stimuli necessary for the appreciation of spatial relations between two or more objects is impaired by unilateral lesions within the right parietal area (see McCarthy & Warrington 1990). De Renzi *et al.* (1971) reported a test of spatial judgement that appeared to demonstrate complete dominance for the post-rolandic region of the right hemisphere.

Loss of topographical memory

Patients with visual object agnosia or visuospatial agnosia may sometimes still be able to visualise familiar scenes or describe familiar routes. However, loss of topographical memory may occur, again in conjunction with lesions in the parietal lobes. Landis *et al.* (1986) and McCarthy and Warrington (1990, pp. 333–337) have reviewed 20 published and 16 new cases of loss of 'topographical familiarity'. While bilateral posterior lesions were common in the group, they concluded that unilateral right-sided posteromedial lesions were critical. Subsequent case reports and functional MRI research has confirmed that the right parahippocampal gyrus is critical for such abilities.

Hécaen (1962) studied the clinical evidence of loss of topographical memory for a previously familiar environment and found that in most cases the parietal lesions were bilateral, though more of the unilateral cases involved the right than the left hemisphere.

Topographical disorientation

Semmes *et al.* (1955) showed that on tasks of following routes from maps, patients with parietal lesions did worse than patients with lesions elsewhere. Ratcliff and Newcombe

(1973) produced especially interesting findings from a study of men with penetrating missile wounds of the brain. Two tests were employed: a visually guided stylus maze task, and a locomotor map-reading task in which the subject was required to trace out a designated route on foot. These were designed to tap visuospatial agnosia and topographical disorientation, respectively. Patients with lesions in the posterior part of the right hemisphere were significantly worse than those with left posterior lesions on the maze-learning test, but a significant deficit on the map-reading test emerged only in those with bilateral posterior lesions. A clear dissociation between the two tasks could sometimes be observed. Ratcliff and Newcombe were led to conclude that while the right hemisphere has a special role in the perception of space, it does not bear an exclusive responsibility for the maintenance of spatial orientation. Bilateral lesions appeared to be necessary before route finding was impaired, perhaps because this involves a constant reorientation to stimuli as the subject moves around and alters his frames of reference. Further experiments on the topic are described by De Renzi (1982), along with a detailed discussion of the various deficits that may contribute to topographical disorientation. An up-to-date synthesis of neuropsychological and neuroimaging data is provided by Aguirre and D'Esposito (1999).

Visual neglect

Unilateral visual neglect (or unilateral spatial agnosia) may be seen in spontaneous drawings, copies, description of pictures, or use of paper when writing. When eating, the patient may ignore food on the left side of the plate. It may also lead the patient to fail to take turnings to the left and consequently he may lose his way on familiar routes. A hemianopia may or may not be present but does not account for the deficit. This is an agnosia for space as such, not merely an agnosia for spatial relations between visual objects. It may be seen in many degrees of severity. It is well confirmed that neglect of the left half of space is very much more common than that on the right, and depends on a right temporoparietal lesion (Heilman *et al.* 1985). In an interesting report Halligan and Marshall (1991) have described a patient who showed severe visuospatial neglect for near ('peripersonal') space but not for extrapersonal space. Following a right middle cerebral infarction he showed left visuospatial neglect, a left hemiparesis and an inferior homonymous quadrantanopia. On standard line bisection tests, performed with the paper immediately before him, he showed marked displacements to the right, but was able accurately to indicate the midpoint of lines and to direct darts accordingly when these were some 2.5 m away. Most current theories of neglect emphasise attentional processes, i.e. the failure to direct attention to one part of space such as the left side (or to disengage it from another). This has led to theoretically motivated rehabilitation programmes, for example involving attentional cueing to the

neglected side, for what is a notoriously disabling syndrome (Pierce & Buxbaum 2002).

In an elegant yet simple study, Bisiach and Luzzati (1978; described in detail in McCarthy & Warrington 1990, pp. 77–97) showed that the neglect of hemispace may affect mental representations as well as perceived space. They asked their neglect patients to imagine standing in the Piazza del Duomo in Milan and to describe the scene from two vantage points: with the cathedral behind or in front of them. In either case it was the buildings on their left that were omitted though knowledge of them was clearly preserved. In an added twist, Marshall and Halligan (1988) showed that some implicit knowledge could affect behaviour despite being explicitly neglected. Flames drawn emerging from the left part of the roof of a picture of a house were ‘not seen’ by a neglect patient who nevertheless stated a preference for an otherwise identical house with no flames.

Auditory agnosia and auditory perceptual defects

In auditory agnosia hearing is unimpaired, as tested by pure tone thresholds, but the patient fails to recognise or distinguish the sounds that he hears. Thus in everyday life he may give the appearance of being ‘deaf’. Typically the onset is with severe dysphasia, which then clears substantially to leave the auditory problem in evidence. The patient is unable to recognise speech, as in pure word-deafness (see earlier in chapter), but in addition cannot recognise non-speech sounds such as the pouring of water, crumpling of paper or jingling of keys. Usually there is also failure to recognise musical sounds. These three defects, word-deafness, auditory agnosia and ‘sensory amusia’, can occur together with varying degrees of severity.

The disorder is extremely rare and few convincing examples have been reported. Vignolo (1969) provides a detailed review, both of the phenomena observed and of their relationships to aphasia. Most examples have been associated with bilateral lesions of the posterior parts of the temporal lobes.

Less complete difficulty with the processing of auditory information may be demonstrated in some patients with brain lesions. Vignolo (1969) showed that patients with right hemisphere lesions fail relatively on tests of discriminating meaningless sounds, whereas patients with left-sided lesions have greater difficulty in identifying sounds to which meaning can be attached. This indicates that the auditory-receiving areas of the two hemispheres are to some extent specialised, that of the right being specifically concerned with grasping the acoustic structure of the auditory input (i.e. subtle perceptual discrimination) and that of the left with endowing the input with meaning by virtue of semantic associative links (i.e. semantic decoding). Analogous differences between the hemispheres have more recently been shown for tactile recognition as well (see under Tactile perceptual defects, next).

With regard to music, the right temporal lobe appears overall to be more important than the left. Right temporal lobectomy has been found to impair performance on tests of musical aptitude, whereas left temporal lobectomy does not (Kimura 1961; Milner 1962). Shankweiler (1966) played extracts of familiar songs to patients who had had temporal lobectomies and found that the group with left lesions had greater difficulty in recalling the titles or words, whereas the group with right lesions had greater difficulty in reproducing or recognising the melody. Using dichotic listening tasks, words fed to the right ear (and proceeding thence by crossed pathways predominantly to the left hemisphere) are reported better than words fed to the left ear, whereas with fragments of melodies the situation is reversed (Kimura 1961, 1964). Moreover, when dichotic tests are given to lobectomised patients it is found that left temporal lobectomy produces a more severe decrement in the contralateral ear where words are concerned, and right temporal lobectomy for the recognition of musical passages (Shankweiler 1966).

Gordon and Bogen (1974) also reported interesting effects when patients were asked to sing familiar songs during the course of unilateral intracarotid amobarbital injections. When the left hemisphere was sedated with the drug the words of the song were severely affected while the melody continued well; in contrast, when the right hemisphere was sedated the words remained relatively intact whereas the pitch and melodic line were severely disrupted.

It seems clear therefore that the right hemisphere is superior to the left in most people for the perception of ‘structured’ musical passages, perhaps with the temporal lobes taking a lead in melody and harmony and frontal areas more involved in pitch, rhythm and phrasing. However, detailed analysis of various components of musical perception (pitch, timbre, discrimination and rhythm) have often given conflicting results, suggesting that neither hemisphere alone is specialised for all aspects of musical cognition and that musical training may confound the results. Lezak (1995) reviews the more recent clinical and experimental evidence, indicating that while the right hemisphere is generally the more important in melodic recognition and chord analysis, the left tends to predominate in the processing of sequential and discrete tonal components of music.

Early functional imaging work showed changes in cerebral blood flow in the right temporal cortex during the perceptual analysis of melodies and of the right frontal cortex during pitch comparisons but, predictably, more recent work has revealed additional complexities implicating wider and more distributed neural networks depending on the nature of the task. Finally, structural MRI has shown that musicians with perfect pitch have greater leftward asymmetry of the planum temporale than non-musicians. Zatorre (2003) summarises the current state of knowledge on music and the brain.

Amusia may be defined as an impairment or loss of musical function deriving from acquired disease of the brain (Henson 1985). Amusia without aphasia has proved to be rare, but examples have been described following right temporal or right frontal lesions. In such examples the deficit usually involves loss of capacity to sing or hum a tune (oral-expressive amusia). Henson (1985) reviews the scattered literature on other amusia syndromes: musical agraphia, musical alexia and musical amnesia, and receptive amusia in which there is failure to discriminate pitch, intensity, timbre and rhythm. This latter disturbance is usually seen only as part of a more widespread auditory agnosia.

Finally, under the heading of 'auditory affective agnosia', Heilman *et al.* (1975) have drawn attention to deficits in the appreciation of the affective tone of speech in patients with right hemisphere lesions. After listening to tape-recorded sentences, patients were asked to judge either the content or the emotional tone in which each sentence had been spoken (happy, sad, angry or indifferent). Six patients had right temporoparietal lesions (with left unilateral neglect) and six had left temporoparietal lesions (with fluent aphasia). The responses were made by selection from a series of line-drawn pictures appropriate to the sentences and emotions concerned. All subjects achieved perfect scores with respect to content, but those with right hemisphere lesions were significantly impaired in judging affective tone (Kucharska-Pietura *et al.* 2003).

Tactile perceptual defects

In tactile agnosia the patient is unable to recognise an object by touch, even though the sensory functions of the hand being tested are normal. The same object is immediately recognised by other means, for example by touching it with the opposite hand or by vision.

There is uncertainty surrounding the distinction between tactile agnosia and the 'astereognosis' of cortical sensory loss, in which there is equally failure of tactile recognition. However, some claim that in tactile agnosia the patient can still distinguish the size, shape and texture of the object even though the object cannot be recognised, whereas in astereognosis the appreciation of these sensory elements is impaired as well.

Commonly, tactile agnosia is restricted to one hand and results from a lesion in the opposite parietal lobe. The supramarginal gyrus has been especially incriminated. Bilateral tactile agnosia is said to follow damage in this region in the dominant hemisphere, and it is possible that in such cases callosal fibres to the opposite lobe have also been destroyed by the lesion. Bottini *et al.* (1995) showed that tactile matching of meaningless shapes (apperceptive recognition) was more affected by right hemisphere lesions, whereas similar matching of meaningful objects was compromised by left hemisphere lesions (associative recognition).

Gerstmann's syndrome

The concept of a 'Gerstmann syndrome' resulting from dominant parietal lobe lesions has become firmly entrenched in the neurological and psychological literature. It consists of finger agnosia, right-left disorientation, dyscalculia and dysgraphia. As such it remains a useful venue for the discussion of these disorders, and yields a useful group of simple clinical tests when one is looking for subtle signs of a lesion in the dominant hemisphere. However, the essential clustering together of the defects has been seriously questioned, and it is now clear that they barely constitute a syndrome in the accepted sense of the word.

It is known that the four components are not always found together, one or more often being absent when the others can be demonstrated clearly. Similarly, one or more components can occur along with other disorders of cognitive function: dysphasia, dyslexia, constructional apraxia, visual disorientation or generalised intellectual impairment. Benton (1961) examined the intercorrelations on tests of the four Gerstmann symptoms and of three other functions related to the parietal lobes (constructional ability, reading and visual memory) in a large unselected series of brain-damaged subjects; it emerged that the correlations of the Gerstmann abilities with each other was no higher than with the three abilities not included in the syndrome. In a separate analysis of patients with damage restricted to the left parietal lobe, the Gerstmann defects again failed to cluster together. Heimburger *et al.* (1964) in a similar study found that as the number of Gerstmann components increased, the lesions tended to be larger in size. When all four defects did appear together they were usually accompanied by severe impairment of many other functions. Nevertheless pure cases do occur rarely. It has not seemed possible to establish a common fundamental disturbance underlying each of the four defects.

Finger agnosia

Finger agnosia is shown by loss of ability to recognise, name, identify, indicate or select individual fingers, either on the patient's own body or on that of another person. Traditionally, the patient is asked to point to named fingers or to name an individual finger, but the presence of dysphasia may confound this simple procedure. Kinsbourne and Warrington (1962) advocated a test in which two fingers are simultaneously touched by the examiner and the patient is asked to state the number of fingers between those touched, first in practice sessions with the eyes open and then with the eyes closed.

The disorder appears bilaterally. The patient does not report it spontaneously, and thus like constructional apraxia it is a defect usually only revealed by specific testing. A lesion in the left parieto-occipital area appears to be critical for its appearance, but it is possible that it can occur very occasionally with right hemisphere lesions. The angular

gyrus and the second occipital convolution have been especially incriminated.

Gerstmann (1958) himself proposed that finger agnosia may represent a minimal form of whole-body autotopagnosia, in other words a defect of recognition of the body or appreciation of the interrelations of body parts (see under Autotopagnosia, later). He suggested that complete autotopagnosia is very rarely seen because those lesions sufficient to produce it also result in concomitant defects that obscure the picture, whereas in the restricted form of finger agnosia it can be recognised as a clear-cut entity. It has been argued (Frederiks 1985) that no other part of the body is verbally differentiated to so great a degree as the hand, and none has such an extensive cerebral representation, hence its special vulnerability that emerges in finger agnosia. A more recent report of 'toe agnosia' calls this appealing theory into question (Tucha *et al.* 1997).

Right-left disorientation

This defect shows as inability to carry out instructions that involve an appreciation of right and left. The patient fails to point on command to objects on his right and his left, to indicate parts of his body on the right and the left, or to perform more complex instructions in which these directions form an integral part of the task. It undoubtedly reflects several complex disorders of function. Gerstmann (1958) suggested that like finger agnosia it represented a restricted form of body image disturbance. Benton (1959) on the other hand stressed that language is likely to be intrinsically concerned with many forms of the disorder. Sauget *et al.* (1971) investigated the relationship between sensory dysphasia and various forms of disturbance including right-left disorientation and finger agnosia, using both verbal and non-verbal tests. They concluded that these disturbances are closely linked to impairment of language comprehension, but that in addition impairment of somatosensory functions is necessary for their appearance. Frederiks (1985) suggests that visual aspects of the body schema, and the relation between corporeal and extracorporeal space, are likely to be fundamentally involved.

Right-left disorientation can generally be accepted as a sign of left hemisphere dysfunction, but is of little value for more precise localisation within the hemisphere. Occasionally, moreover, it may emerge with right hemisphere dysfunction (Benton & Sivan 1993).

Dyscalculia

Dyscalculia is an impairment of the capacity for calculation in persons who have hitherto shown no disorder of their arithmetical faculties, although developmental forms are well recognised (for review see Ardila & Rosselli 2002). It is clear that detailed analysis of the nature of the calculation

defect is necessary if the symptom is to have any localising value since there are many possible sources of failure. Arithmetical ability can be disturbed independently of language functions and general intelligence, but pure cases of this nature are rare. Secondary dyscalculia can result from defects of short-term memory, perseveration or simple impairment of concentration (Butterworth 1999; Cappaletti *et al.* 2005).

Boller and Grafman (1985) subdivide primary dyscalculia into four varieties. First, there may be loss of ability to appreciate the names and significance of numbers or to combine them syntactically to produce a meaningful digit notation. Second, there may be problems with the spatial organisation required in numerical operations. Third, there may be difficulties in carrying out the basic computational aspects of addition, subtraction, multiplication and division (anarithmetica). This last may be subdivided into two sources of failure: inability to retrieve mathematical facts normally stored in memory (e.g. $5+4=9$), or inability to engage in mathematical thinking and reasoning and to understand the procedural rules that underlie mathematical operations.

Such a distinction was clarified by Warrington (1982) in a case study of a physician with a left parietal subdural haematoma. Simple calculations were performed laboriously and inaccurately, and on introspection he found that the processes of addition and subtraction could no longer be performed 'automatically'. He could define the concepts of addition, subtraction, multiplication and division quite well and his understanding of such operations was unimpaired. What he lacked was direct access to the semantic memories of arithmetical facts so that he had to revert to the slow counting processes observed in children. Other anarithmic patients differ from this in that they lack all concept of the mathematical operations, or are unable to comprehend the significance of individual numbers or number facts (e.g. that there are 100 pence in a pound, or that 12 is greater than 11).

Dyscalculia has been found in one form or another with lesions of the frontal, temporal, parietal or occipital lobes of the brain, but the parietal lobes have been most frequently involved and the left lobe more often than the right. This is supported by Grafman *et al.*'s (1982) study in which patients with focal damage to either hemisphere performed significantly worse than controls, but the left posterior brain-damaged group was particularly impaired; this was largely independent of such additional factors as dysphasia or visuoconstructive difficulties. Again, neuroimaging has tended to refine these observations with reference to normal functioning (Dehaene *et al.* 2004).

Disorders of body image

The body image, or 'body schema', may be regarded as a subjective model of the body against which changes in its posture, in the disposition of its parts, and in its soundness or integrity can be appreciated. As such the body image is not static but changes constantly under the influence of internal and external sensory impressions. Moreover, it invariably includes important unconscious as well as conscious components, so cannot be viewed as a mere picture in the mind. Normally it exists on the fringe of awareness, but aspects can be brought into consciousness when subjective attention is focused on them.

The body image is thus an abstract conception, acquired during development and compounded of physiological and psychological elements. Schilder (1935) extended the concept and in particular stressed that data from a wide range of sources must be incorporated into any notion of the body image, including aspects of personality, emotion and social interaction. For him the postural model proposed by Head (1920) represented only a low level of body image organisation, whilst higher levels are built out of instinctual needs and personal interactions.

Disorders of the body image are implicit in a wide range of puzzling and often bizarre clinical states, around which a good deal of controversy exists. Some disturbances represent the influence of structural or physiological changes in the brain, as seen for example in the presence of cerebral disease or in the effects of drugs such as cannabis or lysergic acid diethylamide (LSD). Other disturbances may accompany severe sensory deprivation or psychiatric illnesses such as depression or schizophrenia, and then may appear to be mainly psychological in origin. In some particularly puzzling disorders, such as anosognosia, it is probably necessary to invoke both organic and psychogenic factors in an attempt at a complete explanation.

Body image disturbances associated with brain lesions can be broadly divided into those affecting half of the body only, and those which involve bilateral disturbances. Unilateral body image disturbances are commoner with right hemisphere lesions than left, and the left side of the body is therefore most often affected. They include unilateral inattention, neglect, feelings and beliefs that the left limbs are missing (hemisomatognosia), and lack of awareness or denial of disability (anosognosia). Bilateral body image disturbances are commoner with left cerebral lesions than right. They are usually restricted to finger agnosia (see previous section, under Finger agnosia) or right-left disorientation (see previous section, under Right-left disorientation), but very occasionally there is difficulty in naming or pointing to any body part (autotopagnosia). Complex illusions of bodily transformation or displacement are less closely tied to lesions in known locations and seem to be more intimately involved with non-organic psychopathology. Such non-organic psychopathol-

ogy of body image invariably concerns symmetrical structures (e.g. breasts, buttocks) or those in the midline (e.g. nose, penis), contrasting starkly with their organic counterparts.

Unilateral unawareness and neglect

This represents perhaps the best-known and most frequently encountered change in the body image. For reasons incompletely understood the disorder affects the left limbs in the great majority of cases, and appears to derive particularly from lesions in the neighbourhood of the supramarginal and angular gyri of the right parietal lobe. A spectrum of disturbances is seen, ranging from inattention and unawareness to neglect. Somatic and extrasomatic neglect (e.g. visual neglect) usually occur together but need not do so. Unilateral neglect without visual neglect is rather rare while the reverse is somewhat less so.

The range and interrelationships of these phenomena have been excellently described by Critchley (1953). A minor degree of inattention to the left limbs may require special techniques of examination to reveal it, such as double simultaneous stimulation of both sides of the body together (see Chapter 1, Clinical picture in focal cerebral disorder/Parietal lobes). In unawareness the disorder is more obtrusive, the patient failing to utilise the left hand in bimanual activities or overlooking the left foot when putting on his slippers. When attention is specifically drawn to the left limbs, however, they are used with normal efficiency, or if a degree of paresis exists the patient admits his difficulties. It is as though the limbs of this side were 'occupying a lower level in a hierarchy of personal awareness' (Critchley 1953).

The disorder may involve no more than this or may include the more elaborate symptoms of neglect. The limbs may be ignored in washing or dressing, one half of the face may be left unshaven or the hair uncombed. This is more likely in the presence of confusion or other impairment of intellect. Sometimes unawareness or neglect accompany the development of a hemiparesis, and when this is present the more florid features of anosognosia may be added (see Anosognosia, later).

Such disorders are seen more commonly after acute brain lesions and particularly after cerebrovascular accidents. The degree of unawareness or neglect appears to be related to the abruptness of the lesion, the clarity of consciousness and whether motor weakness is present. Usually these are transient phenomena, and changeable from time to time during clinical examination, but occasionally the disability persists in some form as an enduring defect.

As noted, there is a well-established association between neglect and right parietal lesions, yet typical syndromes of neglect have been reported following damage in other locations such as the basal ganglia and thalamus. More transient states of contralateral neglect may be seen with left hemisphere lesions. The relationship between visual and somatic neglect and their cognitive and neurological underpinnings are set out in detail in Kerkhoff (2001).

Hemisomatognosia (hemisomatoagnosia, hemidepersonalisation, asomatognosia)

In this much rarer phenomenon the patient feels as though the limbs on one side are missing, sometimes episodically but sometimes as a continuous subjective state. It may feature as part of an aura in a focal epileptic attack.

The disorder is accompanied by various degrees of loss of insight. The limbs may feel absent though the patient knows this is not so, or he may say they are absent but can be corrected in his belief, or he may have a fixed delusion that they are absent which cannot be corrected. When consciousness is clear the patient usually retains insight into the illusory nature of the condition, even though it may feel very vivid, and can reassure himself as to the presence of the limbs by feeling or looking at them. In the presence of confusion, however, he may proclaim that the limbs are missing, look for them under the bed, or accuse others of taking them away. The condition is typically due to a parietal lobe lesion of the minor hemisphere and essentially corresponds to the syndrome of unilateral unawareness and neglect described above.

Sierra *et al.* (2002) describe a case of a woman who experienced a generalised sense of depersonalisation following a right subdural haematoma over the parietal lobe following haemorrhage from a carotid aneurysm. She made a good recovery except for mild left arm weakness but felt as if the fingers of her right hand 'did not belong', as if the limbs had disappeared. Furthermore, the patient had the distressing urge to touch or pour hot water over herself for reassurance of her existence. She said: 'Sometimes I do not seem to know who I am, I doubt my own existence. I feel like a piece of furniture.' There was no sensory loss or clouding of consciousness.

Anosognosia

Anosognosia implies lack of awareness of disease and is most commonly shown for left hemiplegic limbs. It may occur along with unilateral neglect, hemisomatognosia or with the illusions of transformation and displacement considered below. It can, rarely, occur in isolation (Jehkonen *et al.* 2000).

In its mildest form the patient merely shows a lack of normal concern for his disability, attaching little importance to it and not grasping its implications. Or when confronted by the disability and obliged to admit it, he belittles the problem and shows an inappropriately flat or facetious reaction (anosodiaphoria). In true anosognosia, however, the patient appears to be completely unaware of the hemiplegia, makes no complaints about it and ignores the inconvenience it causes. In extreme cases, the deficit may be vehemently denied.

Commonly, anosognosia is merely a transient state in the early days after acute hemiplegia has developed, and recedes along with the initial clouding of consciousness. However, it may persist and become more floridly developed with obstinate denial or bizarre elaboration on a delusional basis. When attention is firmly drawn to the hemiplegia, the patient makes some shallow rationalisation for not performing the task, perhaps explaining that he has been ill recently or that he is too tired. In more bizarre cases he insists that the paralysed limbs do not belong to him or attributes them to some neighbouring person (somatoparaphrenia). He may claim that the limbs are some mechanical object, or talk to them and fondle them as though they had an existence of their own (known as 'personification'). Feelings of anger or hatred may be expressed towards them (misoplegia).

A woman of 39 with left hemiplegia, hemianaesthesia and hemianopia was garrulous and confused. She denied that she was paralysed and insisted that her left arm and leg belonged to her daughter Ann, who she said had been sharing her bed for the past week. When the patient's wedding ring was pointed out to her she said that Ann had borrowed it to wear. The patient was encouraged to talk to Ann and to tell her to move her arm; she then became confused and talked vaguely about Ann being asleep and not to be disturbed. When asked to indicate her own left limbs she turned her head and searched in a bemused way over her left shoulder.

The left arm of a patient with a right parietal lesion kept wandering about in the blind homonymous half-field of vision. When the patient wrote, the left hand would wander across and butt in and rest on the right hand. Not recognising this as his own he would exclaim 'Let go my hand!' He would swear at it in exasperation 'You bloody bastard! It's lost its soul, this bloody thing. It follows me around and gets in the way when I read' (Critchley 1964).

Such highly colourful reactions are rare, and it is doubtful whether they occur in the absence of clouding of consciousness or generalised intellectual impairment. They can usually be understood most readily in terms of psychogenic elaboration of some partially perceived defect, sometimes illustrating in unusually clear form the common psychological mechanisms of defence.

Anosognosia is also used as a generic term for imperception of deficits other than hemiplegia. Here again it may range in degree from lack of concern and attention to explicit verbal denial, and again it is often uncertain how far the disturbance is intrinsically related to cerebral disorder alone or how far it reflects superadded psychogenic mechanisms. It is perhaps most commonly seen in relation to aphasic symptoms, classically with primary sensory aphasia when the

patient seems not to appreciate his mistakes. Unawareness or denial of amnesic defects is common as part of Korsakoff's syndrome. Blindness, especially when due to lesions of the optic radiations or striate cortices, may be denied, the patient attempting to behave as though he can see and describing purely imaginary visual experiences when tested (Anton's syndrome). Deafness due to cerebral lesions may more rarely be denied. Unawareness of painful stimuli (pain asymbolia) is another incompletely understood example, in which the patient may perceive a painful stimulus but fails to recognise it as unpleasant, so that little or no defensive reaction is produced. This rare disorder can result from an acquired cerebral lesion, usually in the dominant hemisphere, while other aspects of sensation are unaffected. It has been regarded as a failure to integrate the awareness of pain with awareness of the body image or, alternatively, as a gross denial in the psychogenic sense of painful experience.

The term 'anosognosia' has also been applied in relation to the cognitive deficits in the dementias, both focal and diffuse (see Clare 2004), and to the behavioural problems and personality changes seen after other forms of brain injury (Pirgato 2005), and even movement disorders. Indeed, the similarities between forms of lack of insight commonly observed in people with psychotic disorders and anosognosia has been a major stimulus to research and cross-fertilisation between neuropsychiatry and general psychiatry (Amador & David 2004).

Anosognosia for hemiplegia has been more closely studied than these other forms of the disorder. Nevertheless, the mechanisms involved remain unclear and are the subject of controversy. In the majority of cases there are sensory as well as motor deficits in the limbs concerned, but the condition is not explainable in terms of perceptual deficit alone, since occasionally hemiplegia is denied while the patient remains fully aware of the existence of the limbs. The role of general intellectual disturbance is also disputed. Anosognosia can occur in the presence of strictly focal brain damage and when the patient is mentally clear, although some degree of cognitive impairment or clouding of consciousness is more common. Still others emphasise the psychogenic component, and see anosognosia essentially as a motivated desire to repress the unpleasant facts of a disability. Such primitive defensive behaviour may admittedly be brought to the fore by the presence of cerebral disease.

Weinstein and Kahn (1955) stressed this last point of view in their survey of a large population of brain-injured patients. In addition to denial of the defects already mentioned they noted denial of incontinence and impotence, and patients totally confined to bed might occasionally insist that they had recently returned from a walk. Some degree of mental confusion could always be detected in their patients when specially sought out, though it was often of a subtle nature. Weinstein and Cole (1963) continued these observations in a later study restricted to anosognosia for hemiplegia. Fre-

quently some degree of awareness of the defect was betrayed, and medication or operation was accepted without demur. Common mental mechanisms for defence against anxiety could be seen to operate. The premorbid personalities of the patients had often shown strong perfectionistic traits, tendencies to deny illness, and to view health as important for their self-esteem. Where verbal anosognosia was concerned this often appeared to be an artefact of the interview situation, and the attitudes of observers and of the patient's relatives were important in determining the degree and duration of the denial. The most recent systematic study of anosognosia with hemiplegia was carried out by Marcel *et al.* (2004) on 64 selected stroke patients. They made the distinction between unawareness of paralysis and of its consequences, the latter being more widespread and persistent. Some were unaware of movement failures when they occurred while others were aware but quickly forgot, perhaps due to a failure to update long-term body knowledge memory. Contrary to Weinstein and Kahn, they observed that patients did not generally overestimate other abilities, but they did note that some patients who overestimated current bilateral task ability (e.g. tying one's shoe-laces) when asked in the first-person form did not overestimate when asked how well the examiner, if he was in their current condition, could do each task. Marcel *et al.* concluded that anosognosia for hemiplegia is not a unitary phenomenon.

Against the view that psychogenic factors predominate in anosognosia is the rather obstinate fact that anosognosia, like uncomplicated unilateral neglect, has usually been found to be very much commoner for the left than for the right side of the body. In Starkstein *et al.*'s (1992) series of stroke patients, 38% with left-sided signs showed anosognosia compared with 11% of those with right-sided signs. Moreover, the lesion, when focal, appears to implicate the temporoparietal region rather than the pre-rolandic cortex or lower levels of motor organisation. One complication is that there is no agreed definition of anosognosia, especially where the penumbra of related phenomena are concerned, so assessing prevalence is problematic. This is further complicated in left hemisphere-damaged patients by the presence of aphasia, which might lead to an underestimate of the condition in right hemiplegics (Cutting 1978).

The published work on the cerebral localisation of anosognosia has been systematically reviewed by Pia *et al.* (2004). They concluded that while right hemisphere damage is the hallmark, bilateral damage is frequently reported. Furthermore, the deficit seems to be equally frequent when the damage is confined to frontal, parietal or temporal cortical structures, and may also emerge as a consequence of subcortical lesions. Interestingly, the probability of occurrence of anosognosia was noted to be highest when the lesion involved parietal and frontal structures in combination.

The rarity of anosognosia and related defects in the right limbs is very hard to explain by any theory. It has been

suggested that since the left limbs are normally subordinate to the right, cerebral lesions merely exaggerate this tendency or, alternatively, that with lesions of the dominant hemisphere intellectual deficits and aphasia readily swamp these more subtle manifestations. Others have attempted to resolve the dilemma by proposing that the non-dominant hemisphere is prepotent where the body image is concerned, or at least that it contains special mechanisms for the recognition of unilateral inequalities.

Autotopagnosia

Autotopagnosia refers to an inability to recognise, name or point on command to various parts of the body both on the right and on the left. The defect may apply to other people's bodies as well as to the subject's own, yet other external objects are dealt with normally.

Autotopagnosia in any extensive sense is extremely rare. However, restricted forms are seen in conjunction with many other types of body image disorder, in that a tendency may occur to misidentify certain body parts. Such a defect confined to one body half is seen in patients with unilateral neglect or anosognosia. Finger agnosia (see under Gerstmann's syndrome, earlier) is sometimes regarded as a minimal degree of whole-body autotopagnosia, and to represent the only clear-cut example that cannot be better explained in terms of other defects.

Most examples which implicate the body bilaterally are explainable in terms of apraxia, agnosia, aphasia or disorder of spatial perception. De Renzi and Scotti (1970) described a case which perhaps illustrates essential mechanisms of another type. The patient, who had a tumour of the left parietal lobe, failed to point to body parts, but in contrast could promptly name all parts pointed to by the examiner. He could also correctly monitor the accuracy or otherwise of another person's pointing. The same dissociation between pointing himself and naming could be seen for parts of objects other than the human body, for example for parts of a bicycle. The defect thus appeared to be a part of a more general disturbance of failure to analyse a whole into parts. Autotopagnosia is usually seen in conjunction with diffuse bilateral lesions of the brain. Lesions of the left hemisphere alone can produce it, but must always involve the parieto-occipitotemporal region (Frederiks 1985).

Illusions of transformation, displacement or reduplication

A great variety of body image disturbances may be loosely grouped together under this heading. They are seen in many clinical settings. Some of the less dramatic, such as feelings of heaviness or enlargement of a limb, may occur in healthy subjects in states of extreme exhaustion, sensory deprivation or in the course of falling asleep. Others, like feelings of distortion or free floating of the body, occur with generalised

cerebral disorder as in delirium or under the influence of drugs such as LSD. Many unilateral examples are seen with focal brain disturbance, particularly as part of an epileptic aura, and some of the most bizarre instances, including autoscopia, can occur in the course of migrainous attacks. A further group appear in association with static lesions, particularly those which have led to left hemiplegia and anosognosia, but here again the phenomena are usually short-lived even if recurrent.

Macrosomatognosia and microsomatognosia consist of feelings of abnormal largeness or smallness of parts, or of half or even the whole of the body. Most commonly a single limb or a hand is affected alone. Such changes may be accompanied by sensations of heaviness, distortion or displacement of the part concerned, or features such as these may constitute the sole abnormality. Feelings of swelling, elongation, shortening or twisting may be experienced, rather than a change that preserves the normal proportions of the part. Rarely the experience may be of physical separation of the part from the rest of the body. The following examples are reported by Lukianowicz (1967).

An epileptic girl sometimes had a somatic sensory aura during which she felt that:

my whole body grows very rapidly almost to the point of bursting. After a few seconds it collapses, like a deflated balloon, and then I lose consciousness and have a turn.

A lorry driver discovered to have epilepsy had attacks:

when everything seems to run away from me, and then I get the feeling in my eyes that they tear out of their sockets, and rush out from the cabin, till they touch the people and the houses and the lampposts along the road . . . Then everything rushes towards me again and my eyeballs hurry back into their sockets. At other times I might feel that my hands and arms grow long very rapidly, till they seem to reach miles ahead. A moment later they begin to shrink until they come back to their normal size. I may have such a feeling several times in a minute or two.

A woman with migraine complained:

Before the ache I see coloured zig-zag stripes appearing always from the left side. After a while I begin to feel that my head shrinks until it becomes not bigger than a small orange. At that time it always occurs to me that my head must look like the small dried-up heads of the head-hunters in Borneo, which I had once seen on TV. This sensation lasts about 1 minute and then my head at once comes back to its normal size. This feeling of my head shrinking and expanding goes on for some time, until I get my splitting headache.

The patient almost always retains insight into the alien nature of the experiences, describing the abnormality in 'as if' terms. A truly delusional or hallucinatory experience is rare in the absence of marked impairment of consciousness or psychotic illness. It is of course hard to discern, in cases such as those just quoted, how far the abnormal experience is due to a primary disturbance of the body schema or how far it represents an imaginative elaboration of simple kinaesthetic and vestibular sensory changes. Derangements of either right or left hemisphere function may lead to such phenomena, and when a focal lesion is responsible the parietotemporo-occipital region is said to be usually involved.

Reduplicative phenomena usually involve the limbs, and most often the hand or fingers alone. Such phantoms are usually transient, appearing with darkness and drowsiness. Many cases occur with anosognosia for left hemiplegia, and may lead to illusions of movement in the paralysed limbs. Insight is again usually preserved in large degree, and when the patient looks at the actual limbs the phantom promptly disappears. However, occasional cases are reported in which enduring phantoms prove an embarrassment and inconvenience, and the patient feels obliged to make the real limb coincide in position with the phantom. More dramatic instances of reduplication may involve the whole-body image (Lukianowicz 1967).

Weinstein *et al.* (1954) have reported a few patients with reduplicative phenomena all with cerebral lesions of rapid onset and producing some degree of generalised confusion. One patient with a left hemiplegia claimed to have an extra left hand; one with a left hemiparesis and a fracture of the right leg stated that he had four legs; and one with a severe head injury who had previously had an eye removed claimed to have several eyes. Another patient with a cerebellar astrocytoma and meningitis said that he had three heads and four bodies, one of each with him and the remainder upstairs in a closet. In all four cases the reduplications were accompanied by other forms of reduplication for time, place or person. The 'body image' disturbance therefore appeared to be but one manifestation of a general pattern of reduplicative delusions.

Autoscopy (doppelgänger phenomenon). There is 'a complex psychosensorial hallucinatory perception of one's own body image projected into external visual space' (Lukianowicz 1958). Usually the image is in front of the patient at a certain distance, mostly fleetingly but very occasionally lasting for days at a time. It may be transparent, or coloured and definite, or show expressive movements. It may consist of the whole or only a part of the body, but the face is usually included. Cases have been described in which the image occurs to one side of the midline in a hemianopic field of vision. The experience may be extremely realistic but is almost always recognised by the subject to be a pathological

event. The emotional reaction may be of anxiety or quiet surprise, depending on the patient's mental state.

Usually the experience is visual, as the name implies, but sometimes the body image is experienced as projected into outside space by senses other than vision. A number of subdivisions of this striking phenomenon are recognised, as discussed by Brugger *et al.* (1996).

With *autoscopy hallucinations* only the visual part of the body image is split off, usually being perceived as a lifeless though multicoloured image of the patient's own person. In *heautoscopy*, somaesthetic elements are additionally projected into peripersonal space so that the subject both sees and feels awareness of the presence of his double. The image is then experienced as a living being. The patient may indeed have difficulty in deciding whether he should refer to the phenomenon as 'seeing' or 'being' his double. In an *out-of-body experience*, the core subjective experience is the illusion of being separated from one's body, and visual elements may play a minor role. 'Feeling of presence' occurs without visual elements, the person having the illusion of being accompanied by an invisible being. Typical features include a distinct localisation for the 'presence', as a rule at a specific distance from the subject's own body, also a conviction that the invisible being is real. It is endowed with an intense sense of familiarity and affinity, and sometimes it dawns on the subject that the presence is in fact a replica of himself. Heautoscopy and 'feeling of presence' can occur in close temporal conjunction with one another in certain organic states.

Brugger *et al.* (1996) suggest that autoscopy hallucinations owe most to occipitotemporal lesions and heautoscopy proper to temporoparietal lesions. 'Feeling of presence' may be closely associated with parietal lobe impairment and is often seen along with a sensory hemisindrome or hemispacial neglect. Commonly, however, the associated cerebral pathology is diffuse. With regard to laterality, Brugger *et al.* suggest that the visual doppelgängers (autoscopy hallucinations and heautoscopy) occur more often with right hemisphere lesions than left, whereas out-of-body experiences are projected more often towards the right and presumably reflect left hemisphere dysfunction. In their analysis of 31 cases of 'feeling of presence', Brugger *et al.* found that the presence was typically confined to one hemispace and was rather more often lateralised to the right than the left; of 12 cases with unilateral brain lesions, eight were in the left hemisphere and four in the right.

Phantom limb, which occurs after amputation or peripheral lesions of the nervous system, has a basis quite distinct from the supernumerary phantom that occurs with cerebral disease (Halligan *et al.* 1993). It is nonetheless in some ways the most decisive proof of the existence of the body schema. Phantom limbs are seen most commonly after amputation, but similar phenomena may follow severe nerve plexus lesions or lesions of the brainstem and thalamus. Equivalent phantom phenomena have also been reported after removal of the breast, the genitalia or the eye.

Halligan (2002) provides a comprehensive review of the phenomenon throughout history to the present day and its implications for cognitive neuropsychiatry. Distinction must be made between the perception of the missing limb itself, including its spatial characteristics, and the perception of phantom limb sensations such as paraesthesiae, heaviness, cold, cramp and pain. If the phantom is to develop, it usually does so immediately after amputation, persisting sometimes for several months and sometimes for the rest of the patient's life. It has a markedly realistic character, can usually be 'moved' at will, and may assume a relaxed or a cramped position. In the course of time it may appear only sporadically, or it may gradually telescope, the distal portion ultimately approaching the stump and disappearing into it.

Pain in the phantom limb can be distressing and intractable. It is typically paroxysmal, burning or shooting in character, sometimes occurring alone and sometimes with paraesthesiae. As with other phantom limb sensations the pain may be markedly affected by influences such as a change in the weather, use of a prosthesis, use of the contralateral limb, pain elsewhere in the body or firm efforts at mental concentration. A topographically organised sensory representation of the phantom limb may develop (remapping), for example on the face or chest, stimulation of which may be experienced in the phantom and which may be detected using functional neuroimaging in the corresponding sensory cortical region.

A psychogenic component thus undoubtedly exists, and has been interpreted in terms of loss of bodily integrity and reaction to disablement. The current emotional state may have a profound effect, depression contributing to such an extent that electroconvulsive therapy (ECT) has sometimes been found to abolish phantom limb pain. Psychotherapy and hypnosis have accordingly sometimes met with success in treatment, as has sensory distraction. However, a physiological component is also indicated by the efficacy, short-lived though it may be, of surgical procedures. Relief may follow the excision of a stump neuroma, chordotomy, or lesions in the thalamic radiation or sensory cortex.

Body image disturbances in non-organic psychiatric illness

This area has rarely been examined systematically, and Luki-anowicz's (1967) survey of 200 consecutive admissions to a mental hospital, 31 of whom complained spontaneously of unusual sensations and experiences in various parts of their bodies, provides a valuable set of observations.

Disturbances of the shape of the body image were the commonest abnormality and took many forms. In schizophrenia patients there were examples of feelings of change of shape to that of another animal, the hands feeling shrunken like crab's claws or the whole body feeling as though transformed into a dog. Such changes appeared to be based essentially on

misinterpreted bodily sensations, combined often with hallucinations of the sense of smell. Insight into the unreality of the experiences was commonly retained, though sometimes incompletely expressed. In some cases complex sensory experiences appeared to underlie feelings that the body was changing into that of the opposite sex, likewise in some examples of transformation into Christ or other figures. Care was taken to distinguish as far as possible between mechanisms such as these, in which there was a discernible relationship to corresponding bodily sensations and hallucinations, and the more usual situation in which a delusional belief in a new identity or sex was purely ideational.

Feelings of change of position in space included levitation, floating and falling, sometimes as hypnagogic phenomena but sometimes occurring in the full waking state. In epileptic patients equivalent sensations were sometimes observed as a kinaesthetic aura preceding an epileptic attack.

Feelings of reduplication and splitting occurred in schizophrenia and in depression.

A schizophrenic student had the feeling of:

two bodies, one outside the other, only a bit larger than my actual body. I feel that the 'inner' body is the real one, and the 'outer' is more like something artificial, a sort of shell over a hermit crab although it has the shape and the appearance of my 'real' body.

A woman when depressed had a feeling:

as if my body was split into two halves, like a stem of a tree struck by lightning. They both feel a few inches apart and there is nothing between them, but a black empty hole; black and empty and dead.

Again, in epileptic patients such experiences could herald an attack. Experiences of autoscopic doubling were also seen in patients with schizophrenia and depression.

Feelings of additional body parts occurred in several bizarre forms, sometimes inviting a psychodynamic formulation which would see them as symbolically representing displaced sexual organs (but see Halligan *et al.* 1993).

A man whose potency was dwindling as a result of spinal injury developed recurrent depressive episodes. In one there were visual and haptic hallucinations of spurs and horns growing from his ankles, in another of a ball sticking out of his thigh, and in another of big screws growing from his abdomen and thighs. He retained insight into their unreal nature, and ECT was effective in banishing the phenomena along with the depression.

Change of size sometimes affected the whole body, and sometimes parts only, such as the ears, nose or limbs. Again, displaced sexual symbolism sometimes provided the most ready explanation, though analogous examples occurring in the course of epileptic and migrainous attacks may have rested primarily on disturbed cortical function. Lilliputian experiences were rare in comparison to feelings of enlargement, but one depressed woman had distressing hypnagogic experiences in which she felt her body shrink rapidly to the size of her little finger.

Changes in mass were usually manifest as feelings of emptiness and hollowness of body parts, particularly of the head. They were confined to patients with depressive illness or neurotic disorder, and often came close to nihilistic delusions. The following case illustrates the possible distinction.

A man with an anxiety disorder described a recurrent hypnopompic experience as follows:

Just after I wake up, but before I move, I have a terrifying feeling that my whole body consists of skin with nothing inside, like an empty blown-up balloon, or an empty shell, only pretending to be a human body. It is a very frightening feeling, which lasts only a few seconds and disappears immediately when I move any part of my body.

In general these various disturbances in psychiatric patients seemed to be an integral part of their mental illnesses, along with the more common hallucinations and related psychotic symptoms. Successful treatment of the psychiatric illness invariably resulted in resolution of the body image disturbances.

More recently, Cutting (1989) has analysed body image disturbances in a series of 100 schizophrenic patients. Rather surprisingly almost half had experienced some form of disorder, the predominant subjective change being alterations in structure, weight or shape. Other abnormalities included tactile hallucinations, feelings of additions to the body, or belief in the presence of localised devices within the body. As expected many of these changes were highly bizarre. Consonant with Cutting's (1985, 1990) view that right hemisphere dysfunction is important in the pathogenesis of schizophrenia, 13 of the 14 instances in which the disorder was lateralised concerned the left side of the body.

As noted earlier, however, non-organic and particularly non-psychotic disorders of body image frequently affect midline structures and probably relate to exaggerations or distortions of common, culturally influenced preoccupations. For example, personal appearance or an aspect of body image becomes the focus of obsessional rumination, or overvalued ideas, and may lead to requests for surgical interven-

tion, or may dominate eating behaviour as in anorexia nervosa. Again, treatment should be aimed at the underlying disorder.

Non-cognitive disturbances and regional brain dysfunction

The forms of disability discussed above have all been more or less closely tied to cognitive or perceptual deficits, even though these have sometimes been of a rather subtle nature. There remain, however, certain abnormalities of emotion, behaviour and 'personality' that appear to be related to regional brain dysfunction yet do not necessarily have cognitive disturbance at the core. These are clearly of special interest to the psychiatrist. Certain examples have been selected for discussion.

Abnormalities of emotion and personality cannot be assessed with anything like the precision that is usually possible for cognitive defects. It has already been seen how much uncertainty surrounds our understanding of such measurable disorders as memory impairment, and such testable defects as aphasia or apraxia. With the body image disturbances there is an uncertain admixture of physiogenic and psychogenic mechanisms to be considered. Such problems are greatly extended in any analysis of disordered emotion or abnormalities of personality and social behaviour. Despite such difficulties important leads have been obtained, and interesting clinicopathological correlations have emerged in the examples discussed below.

Disordered control of aggression

Aggression is commonly divided into 'defensive' and 'predatory'. In extreme form this may be manifest as outbursts of uncontrollable violence. In some instances such disturbance is clearly attributable to focal cerebral pathology: in relation to epilepsy, certain cerebral tumours and other forms of brain disease. But the argument has been extended to suggest that in some habitually aggressive individuals, not showing overt signs of cerebral disorder, there may be abnormalities of the neural apparatus subserving aggressive responses. Attention has been directed particularly at possible dysfunction of the 'limbic brain' and especially of the amygdaloid nuclei within the temporal lobes. This remains a contentious area, not least because of the frequent difficulty in apportioning blame between pathophysiological and psychosocial influences in clinical situations, as discussed below.

In seeking correlates between aggressive behaviour and brain pathology, one is handicapped by the difficulty of defining in what circumstances and to what degree aggression must be displayed before it is regarded as abnormal. A variety of motivations may be involved, and many aspects of aggression are biologically valuable in humans as in other animals. Its determinants include environmental, social,

cultural and intrapsychic factors, also learned components, any of which can emerge as crucial in individual instances. However, there appear to be persons who are subject to recurring and harmful outbursts of aggressive behaviour, sometimes on little or no provocation, and certain aggressive offenders whose episodes remain inexplicable in terms of personality, social adjustment and the situation at the time. Here it would seem that there may be important cerebral determinants of this pattern of behaviour: an abnormal triggering of aggressive responses based in disturbed cerebral functioning (Filley *et al.* 2001).

Neural substrate for aggressive responses

A neural substrate for the elaboration and display of aggression has been amply demonstrated in both animals and man. A large literature exists to show that in animals aggressive behaviour can be facilitated, decreased or abolished by cerebral lesions, mostly situated in or near the limbic system and hypothalamus. Bard (1928), for example, showed the importance of the caudal half of the hypothalamus for the elaboration of 'sham rage' in decorticate cats, and Klüver and Bucy (1939) demonstrated an abnormal absence of anger and fear after bitemporal lesions in monkeys. Downer (1962) elegantly showed how removal of the amygdaloid nucleus from a single temporal lobe would, after section of the cerebral commissures, allow the monkey to display normal aggressive behaviour when stimuli were fed to the sound hemisphere but unnatural tameness when fed to the lesioned side.

Delgado's work was particularly impressive in illustrating the need to take into account both intracerebral mechanisms and socioenvironmental factors in the understanding of aggressive behaviour in animals (Delgado 1969). Radio-stimulation via implanted electrodes in the amygdala, hypothalamus, septum and reticular formation allowed discrete areas of the brain to be stimulated while monkeys and chimpanzees were free-ranging and interacting with their fellows. Certain areas when stimulated produced a threatening display or social conflict, but this depended on the hierarchical position of the animal in the group; such responses could be observed when a submissive monkey was at hand as a target, but were inhibited in the presence of a dominant animal. Moreover, elicited behaviour that might be interpreted as aggressive by the experimenter was apparently not always perceived as such by the other animals in the colony.

Clinical evidence

Some of the principal evidence has come from studies of patients with epilepsy. This is set out in Chapter 6, where the question of a special association between temporal lobe epilepsy and aggressive behaviour is discussed (see Crime and epilepsy). A proportion of patients with temporal lobe epilepsy appear to show explosive aggressive tendencies, not only in relation to attacks but as an enduring trait of their per-

sonalities. Temporal lobectomy carried out for the relief of epilepsy may be followed by pronounced improvement in the control of such disorder.

When patients with and without 'affective aggression' are contrasted, the former generally turn out to have more cognitive impairments and other psychiatric symptoms. Using MRI, van Elst *et al.* (2000) showed that at least a subgroup of the aggressive patients did not show evidence of mesial temporal sclerosis, but had marked atrophy of the amygdala. A separate report from the same research group (Woermann *et al.* 2000) using voxel-based analysis of MRI showed more distant left frontal grey matter volume deficits in the aggressive group, presumably contributing to the behavioural manifestation.

Patients with cerebral tumours have occasionally been observed to show abnormal outbursts of rage and destructive behaviour. Poeck (1969) reviews the literature, showing the frequent involvement in such cases of the hypothalamus, septal regions and medial temporal structures including the hippocampus and amygdaloid nucleus. Some patients have described their condition as a feeling of rage building up in spite of themselves, others as waiting tensely for the first opportunity to release their accumulated aggression. However, Poeck stresses that the relation between symptoms and lesions is by no means strict and constant. Important additional factors derive from the premorbid emotional make-up, and the presence or absence of diffuse brain damage.

A patient reported by Sweet *et al.* (1969) showed in very striking fashion the possible relationship between a circumscribed tumour and the wildly aggressive behaviour that ultimately ensued. The case also illustrates the complex nature of 'aggressive' behaviour in humans in general, and the hazards of attempting a simplistic formulation of the nature of the link between such behaviour and cerebral pathology.

In August 1966 a young man murdered his mother and wife in their apartments, then ascended the University of Texas tower, stepped on to the parapet and killed by gunfire 14 people, wounding 24 others. In his personal diaries he had recorded over several months that something peculiar was happening to him, which he did not understand but which he was noting down in the hope that its mention would help others to do so. Five months before the mass murder he had consulted a psychiatrist, stating early in the interview that sometimes he became so mad he could 'go up to the top of that University tower and start shooting at people'. Autopsy disclosed a glioblastoma multiforme; the damage to the brain from the gunshot wounds that terminated his barrage led to uncertainty about the precise location of the walnut-sized tumour, but it was considered to be probably in the medial part of one of the temporal lobes.

Other examples of an association between a lowered threshold for aggression and brain pathology include patients who become seriously disturbed as a result of birth trauma, head injury and intracerebral infections. However, in such situations clinicopathological correlations are rarely exact enough to allow firm conclusions to be drawn about the role of circumscribed as opposed to diffuse brain damage. Moreover, there will often be intervening variables by way of affective disorder or paranoid psychosis, especially when serious violence is involved (Gunn 1993). Tonkonogy (1991) performed CT and MRI in a mixed group of patients with organic psychosyndromes who had shown repetitive violent behaviour; in 5 of 14 patients, focal lesions were observed in the anterior temporal lobe structures close to the amygdala, most often attributable to head injury. The questions of impaired control of aggression after head injury is further discussed in Chapter 4 see under Aggression and of antisocial conduct after encephalitis lethargica in Chapter 7.

Opportunities for assessing the effects of stimulating discrete brain structures in humans have occasionally appeared to yield direct evidence for the role of limbic structures in elaborating emotional responses, including short-lived feelings of rage. Heath *et al.* (1955) stimulated the amygdaloid nucleus via implanted electrodes in a chronic schizophrenic patient, resulting in a sudden rage response when the current reached a certain intensity. She was perfectly aware of her feelings and was able to discuss them objectively between stimulations. The result was unstable, however, and later stimulation of the same point produced feelings of fear in place of rage. Delgado *et al.* (1968) found that stimulation of the amygdala and hippocampus in patients with temporal lobe epilepsy produced a variety of effects including pleasant sensations, elation, deep thoughtful concentration, relaxation and colour visions. However, in one patient with postencephalitic brain damage and epilepsy, stimulation of the right amygdala led to episodes of assaultive behaviour reminiscent of her spontaneous outbursts of anger: 7 seconds after the stimulation she interrupted her activities, threw herself against the wall in a fit of rage, then paced around the room for several minutes before resuming her normal behaviour. During the elicited rage attack no seizure activity was evident on depth recording. The observation proved to be of crucial importance for selecting the appropriate site for a destructive lesion within the temporal lobe. Fenwick (1986) reviews other early studies of this nature.

Psychosurgery for aggression

It thus seems fair to conclude that pathological derangements affecting the limbic areas, and perhaps especially the amygdaloid nuclei, are capable of leading to abnormal tendencies towards aggressive behaviour in humans. The conclusion has led to attempts at modifying such behaviour by a variety of psychosurgical procedures. Unilateral temporal

lobectomy can meet with success in patients with temporal lobe epilepsy, as already mentioned, but bilateral operations are contraindicated by the severe memory deficits that follow. However, Turner (1969, 1972) reported success with bilateral division of tracts within the temporal lobes and with posterior cingulectomy, mostly in patients with temporal lobe epilepsy but also in some abnormally aggressive patients who had never had seizures.

Attention has also been directed at stereotactic operations on the amygdaloid nuclei in patients with temporal lobe epilepsy and violent behaviour (Hitchcock *et al.* 1972; Mark *et al.* 1972). The results were reported as often markedly successful, and without disabling side effects. Narabayashi performed amygdalectomies on one or both sides in a large population of patients, some with epilepsy and some with 'severe behaviour disorders and hyperexcitability' (Narabayashi *et al.* 1963; Narabayashi & Uno 1966). Nearly all were mentally subnormal. Generally positive results were claimed. It is hard in these reports to discern how specific were the effects on aggressive behaviour, and how far the improvements may have been related to improved control of epilepsy. An enormous series has been reported by Ramamurthi (1988) in India of 481 cases of bilateral amygdalotomy and 122 with mostly secondary posteromedian hypothalamotomies for otherwise untreatable aggression. Good results are asserted on three-quarters of the cohort which, it is claimed, persisted in the majority at 3 years. Naturally, randomised and double-blind evaluation of such treatments are difficult to achieve but one cannot be confident that these results are generalisable to clinical practice in most parts of the world. Advances in psychopharmacology combined with the social controversy surrounding psychosurgical treatments, especially when applied to minors and to persons held in custody on account of offences, means that such approaches are likely to be seen increasingly as an absolute last resort.

Habitually aggressive offenders

We must now consider the situation in individuals who display persistently aggressive behaviour yet who lack overt evidence of brain pathology. These are the persons traditionally labelled as 'aggressive psychopaths' or as having an 'explosive personality disorder'. Their outbursts of violence are usually merely a part of wide-ranging personality and social maladjustments. They are notoriously resistant to efforts at therapeutic intervention, yet many seem to outgrow their aggressive propensities in middle years. It is obviously a matter of importance to attempt to clarify whether in some such persons there are definable abnormalities of the neural apparatus subserving aggressive responses, and to what degree such abnormalities are inherited or acquired.

It has been known for many decades that a high proportion of persons with disturbed personalities, especially those who show aggressive antisocial behaviour, have abnormal

EEGs. Such EEG abnormalities involve the temporal lobes particularly, are often of a type suggesting cerebral immaturity, and tend to decrease with age in parallel with improvements in behaviour. Hill (1944) found that the abnormalities in aggressive psychopaths were often bilateral, synchronous, and postcentral in location, suggesting dysfunction in subcortical centres or the deep temporal grey matter.

Williams (1969) reinforced the importance of earlier findings. In a review of EEGs carried out on over 300 men convicted of violent crimes, he found that of those who had a history of habitual aggression or explosive rage, 65% had abnormal EEGs. When persons with disabilities suggesting structural brain damage were excluded (i.e. those who were mentally subnormal, had epilepsy, or with a history of major head injury) the figure remained high at 57%, around four to five times higher than in infrequently violent people from the same sample.

Since the early EEG studies, the full armamentarium of neurological investigations has been applied to people with serious aggression. This has been thoroughly reviewed recently with an emphasis on frontal lobe dysfunction (Brower and Price 2001). The participants in such studies tend to be drawn from a variety of settings, from the community to specialist forensic psychiatric units. The nature of the sample has a great bearing on the results, as does the extent to which potential confounding factors, such as drug and alcohol abuse, psychosocial deprivation, psychiatric disorder, epilepsy and legal implications, are taken into account. Most neuropsychological studies do indeed show an association between violent behaviour and executive deficits but the association is rather non-specific. The review cites studies using MRI that have shown, for example, reduced prefrontal grey matter volume in a small group with antisocial personality disorder even in comparison to a substance-dependent control group. A further study using FDG-PET on 41 'murderers' revealed reduced metabolic activity in prefrontal (and left subcortical) structures and this seemed to apply most to those without psychosocial risk factors for aggression and whose pattern of behaviour was of the non-predatory type (Brower & Price 2001). There is insufficient evidence to point more precisely to areas in the cortex or even prefrontal cortex that might subserve aggressive behaviour, but the authors suggest that dorsolateral and medial frontal abnormalities may relate to aggression of the impulsive versus unempathic varieties, respectively.

Episodic dyscontrol (intermittent explosive disorder)

After excluding patients who have demonstrable epilepsy, brain damage or psychotic illness as a basis for their aggressive acts (also those pursuing a motivated career of premeditated crime for gain), one is left with a number of persons who may be victims of their disturbed cerebral physiology. The essence of the claim is that violent behaviour can, in effect, be the only overt symptom of brain disorder.

The great majority of such persons are male, from seriously disturbed family backgrounds, and with a history of repeated outbursts of violent behaviour dating back to adolescence or even childhood. Provocation for such outbursts has often been minimal. Evidence of minor neurological dysfunction is not uncommon and there is a high frequency of abnormal EEGs, often involving the temporal lobes and sometimes quasi-epileptic in nature. Many have symptoms reminiscent of epileptic phenomena, even when not suffering from seizures; in particular the outbursts may be preceded or followed by features akin to those seen with temporal lobe epilepsy. The implication is that such persons have functional abnormalities of the neural systems subserving aggressive responses, which set the threshold for the elicitation of outbursts at an unusually low level.

Such a 'syndrome' appears to stand at the borderland between what is conventionally regarded as psychopathic personality and what with more definite clinical evidence might be included as temporal lobe epilepsy. Clear definition of the syndrome, and estimates of its frequency, are rendered difficult by the elusive nature of the ancillary evidence of cerebral dysfunction, and the ever-present confounding evidence of social and interpersonal stresses in the group.

The status, and indeed the existence, of the syndrome remains a matter of controversy. Some regard the concept as useful in clinical practice, which may benefit from treatment in its own right (Olvera 2002), while recognising that it cuts across traditional diagnostic boundaries (Elliott 1992). Others regard it as serving no useful purpose. Lucas (1994) presents a detailed review of the evolution of the concept and concludes that its nosological status is invalid. He stresses that it lacks clear demarcation from allied forms of disordered behaviour, and suggests that it represents one extreme of a continuum rather than a distinct nosological category.

Schizophrenia

Schizophrenia has proved to be an increasingly fruitful arena for neuropsychiatric research. Ever since its earliest delineation from Kraepelin's time, an organic contribution to the disorder has been suspected and is now increasingly accepted. Some thinkers have even gone so far as to predict that schizophrenia will soon be seen as quintessentially neuropsychiatric, the first in a wave of classical psychiatric disorders to be reclassified in a brave new era of enlightenment and pathophysiologically based diagnoses. So far this has not happened. What has occurred is that following a massive if uncoordinated international research effort, the brain basis of schizophrenia has become an essential part of the tenets of mainstream general psychiatry no longer requiring the prefix 'biological' or 'neuro-'. Hence, some mention of the neuropsychology, neuroanatomy, neurophysiology, neurochemistry and neuropathology of schizophrenia is to be expected in any manual of psychiatry and even a cursory dis-

cussion of the current state of evidence in each of these areas could stretch to many volumes. It may be that, over the horizon, there will be a discovery that renders much of this information redundant, so that in the next edition of this textbook a few concise paragraphs will be all that is required to outline the genes, brain systems, neurotransmitters and proteins that cause schizophrenia, followed over the page by the cure. Alas, for the time being it not possible to predict what promising avenues will lead to dead ends and what marginal observations will turn out to be breakthroughs.

What follows therefore is a highly partial account of schizophrenia through the filter of clinical neuropsychiatry. This comprises, first, a picture of schizophrenia as a neurological disorder, with emphasis on its associated cognitive and neurological deficits (with heavy reliance on MRI). Next, the symptomatic schizophrenia concept is discussed. The latter presents regularly in clinical contexts, for instance when investigation of a patient diagnosed with schizophrenia brings to light a significant brain or toxic abnormality. Finally, some implications of research in schizophrenia for the rest of neuropsychiatry is outlined.

Schizophrenia and neuropsychological impairment

The earlier term for schizophrenia, 'dementia praecox' (pre-mature dementia), makes it clear how central cognitive impairment was to the early conceptualisation of the disorder. What has remained contested is whether such impairment is confined to some functions while sparing others and what is its temporal sequence. That is, is it there premorbidly, at the onset of the illness and does it accumulate as the disorder progresses?

When patients with chronic schizophrenia are assessed with a 'standard' clinical neuropsychological battery, their performance does not distinguish them from other neurological cases, including those with amnesia (see Memory disorder in the psychoses). Furthermore, elderly patients with schizophrenia will, on average, perform as badly on neuropsychological tests as patients with moderate Alzheimer's disease, with only marginally superior memory and inferior executive and motor functions (Davidson *et al.* 1996). Unselected convenience samples of schizophrenia patients will usually show impairments on a range of cognitive test between 1 and 3 standard deviations below the population mean (equivalent to 15–45 IQ points) and recent work on patients in their first episode confirms that much of this impairment is present from the beginning (Heinrichs & Zakzanis 1998; Bilder *et al.* 2002). Consistent with this is the failure to find marked cognitive decline following the first episode up to 5 years later. The very latest research using serial structural MRI measures is beginning to challenge this. There appears to be a general loss of brain substance (grey more than white) in patients with schizophrenia after their first episode, which seems to represent an acceleration of the normal age-related decline. This may be a strand of evidence

in favour of a 'neurodegenerative' element to schizophrenia (see below) but currently attention is focusing on the possible effects of medications, particularly typical or first-generation antipsychotics (Lieberman *et al.* 2005).

Premorbid and illness- and symptom-related cognitive deficits

One of the few consistent findings in the literature is that people destined to develop schizophrenia show, as a group, delayed developmental milestones and social development, plus inferior academic performance at school and on cognitive tests, in comparison to their peers. Studies that have compared schizophrenic-to-be children with their siblings have confirmed patients' lower premorbid IQs but reveal a less marked discrepancy than when classmates are used for comparison. The greatest discrepancy arises when schizophrenic-to-be children are compared with population norms (Aylward *et al.* 1984).

Getting an accurate picture of premorbid deficits in routine clinical practice is difficult unless school reports over many years have been retained. Tests of reading ability, such as the National Adult Reading Test, have been shown to be relatively immune from acquired cognitive decline so may serve as a proxy for premorbid ability (Crawford *et al.* 1992).

By far the strongest evidence comes from longitudinal birth cohorts from the UK and conscript cohorts from Sweden and Israel. The National Survey of Health and Development (Jones *et al.* 1994) comprised a random sample of all UK births in a single week in March 1946 (approximately 5000) and was studied on 19 occasions between the ages of 2 and 43 years on a number of health and social variables. Cases of schizophrenia (30 meeting DSM-III-R criteria) were identified in the course of these assessments and from a register of psychiatric hospital admissions. The cases tended to score lower on all tests of educational abilities carried out at ages 8, 11 and 15, the deficit increasing with age. The other cohort was started in 1958 and became known as the National Child Development Survey (Done *et al.* 1994). It too consisted of all births in a single week. Individuals were assessed at ages 7, 11 and 16 on a large variety of health, psychological and social variables. There were approximately 40 such cases who met 'narrow' schizophrenia criteria and these were contrasted with a comparable group of pre-affective disorder and pre-neurosis children. The pre-schizophrenics showed a stable pattern of psychometric test score deficits equivalent to around 8–9 IQ points.

A cohort of Swedish men conscripted into the armed forces in 1969 has been followed up to the age of 43. Of around 50000, some 362 developed schizophrenia (Zammit *et al.* 2004). There was a strong linear trend which showed that the lower the IQ was at age 18, the greater the risk of schizophrenia, with an approximately 10-fold difference between a low-borderline IQ and a superior IQ. It was as though the whole population of pre-schizophrenics had an IQ shifted

downwards by 5–10 IQ points. This pattern is not seen in bipolar disorder. When the individual tests were examined there was a hint that verbal tests and those which required a degree of planning and strategy were more sensitive to the cognitive problems associated with schizophrenia but the overall finding was of a non-specific cognitive impairment (David *et al.* 1997). Note that cognitive functioning could not be regarded as ‘abnormal’ at this time.

The Israeli conscript cohort studies comprised both men and women and involved 536 people with schizophrenia (Reichenberg *et al.* 2002). Again, the results were remarkably consistent, with those destined to develop schizophrenia scoring lower on a range of tests, be they non-verbal such as the Raven’s Progressive Matrices, or verbal, arithmetic or abstract reasoning (speaking and reading being spared). The effect sizes were between 0.2 and 0.6, which can be roughly translated into a 4–8 IQ points deficit. It should be noted that these cohort studies made efforts to control for behavioural and social problems, which might have confounded the results, and for prodromal decline. Hence cognitive efficiency is clearly suboptimal prior to the onset of schizophrenia but not in a way that could easily be detected clinically because it is neither particularly marked nor unusual in its pattern. This raises the question as to how this subtle cognitive dysfunction turns into the large neuropsychological deficits affecting patients with the disorder. Very few longitudinal studies have spanned the premorbid and postmorbid phases of the illness, an exception being that by Caspi *et al.* (2003) on the Israeli conscripts. They showed that when individuals were retested after a single episode of schizophrenia on the same battery of tests they had when inducted into the army, they tended to show a drop in reasoning, mental speed and concentration; if not, they certainly failed as a group to show any improvement on the tasks, which, however minor, was seen in the healthy control conscripts.

The remaining illness-related neuropsychological deficits prominent in cross-sectional studies of patients is yet to be fully explained. As implied above, it applies to established cases, as well as first-onset and drug-free patients (Saykin *et al.* 1994) and there is surprisingly little resolution after the episode has abated (Censits *et al.* 1997). Nevertheless some of the decline can probably be put down to the unfortunate combination of lost opportunities, physical illness, substance misuse, medication, lack of motivation, social isolation and selection factors, although why a small number of patients show a massive decline in intellectual functioning, sometimes in spite of relatively good symptom control, remains a mystery.

Generalised or specific?

Prior to the onset of schizophrenia it is clear that most if not all cognitive functions show some compromise. The same is true in the full-blown disorder (Heinrichs & Zakzanis 1998) but it has repeatedly been claimed that some test scores seem

to be disproportionately impaired and others relatively spared, i.e. there are specific neuropsychological deficits. Visual perception, recognition, naming and procedural or motor learning are relatively spared while executive functions (including working memory, tasks of set-shifting, ignoring irrelevance, forward planning) and memory (Aleman *et al.* 1999), especially verbal and semantic, tend to be the functions more obviously affected. Hence it is not unreasonable to begin to talk of a schizophrenia profile. The Wisconsin Card Sorting Test is widely regarded as a test of frontal lobe/executive functioning (see Chapter 3, under Frontal lobe (‘executive function’) tests) and has been used frequently in studies of schizophrenia. Patients tend to perform badly, and this is interpreted as evidence of a specific frontal/executive deficit. However, the counter-argument is that given the general intellectual demands of the task in terms of working memory and sustained attention, as well as set-shifting and response inhibition, such an inference may be questioned. Indeed Dickinson *et al.* (2004) showed that most of the cognitive impairment in patients could be explained by a single factor (cf. IQ).

One reason why more specificity has not emerged may be that the ‘schizophrenias’ are heterogeneous at the cognitive level and that separating patients according to symptom pattern or syndrome might clarify the matter. Liddle (1987) found that symptoms of schizophrenia aggregated into three broad clusters: psychomotor poverty (affecting speech and movement and blunting of affect); reality distortion (essentially positive symptoms, hallucinations and delusions); and finally disorganisation (including thought disorder and inappropriate affect). Using a battery of neuropsychological tests, he showed that psychomotor poverty was associated with poorer performance on abstract reasoning and long-term memory tests, disorganisation on impairments of attention and learning, while the reality distortion symptoms correlated with impaired figure-ground perception (traditionally temporoparietal tests). Subsequently, Liddle *et al.* (1992) employed functional neuroimaging techniques to corroborate these clusters. ¹⁵O-PET indices of resting regional cerebral blood flow (rCBF) were measured in cohorts of chronic schizophrenic patients with contrasting patterns of symptomatology. Patients classified as having the *psychomotor poverty syndrome* (i.e. poverty of speech, flattened affect and decreased spontaneous movement) showed decreased rCBF in the left prefrontal and parietal cortex, along with increases in the caudate nuclei. The area of left prefrontal hypoperfusion coincided with that shown by Frith *et al.* (1991) to be activated by the internal generation of willed as compared with routine actions. Patients with the *disorganisation syndrome* (disordered thought and inappropriate affect) showed increased resting rCBF most markedly in the anterior cingulate region. This coincides with the area maximally activated during performance of the Stroop test, in which competing responses must be suppressed (see Chapter 3, under Stroop tests); hence it may reflect a struggle in such

patients to suppress inappropriate mental activity. Patients with the *reality distortion syndrome* (delusions and hallucinations) showed increases in rCBF most prominently in the left parahippocampal gyrus and contiguous areas. In each syndrome the detailed patterns of blood flow indicated that distributed neuronal networks rather than specific loci were implicated in the underlying abnormalities of brain function.

Much work has been done along these lines. At the risk of not doing justice to this work, a broad summary might be that, in general, standard neuropsychological tests do not show noticeable correlations with key symptoms such as hallucinations and delusions. Experimental paradigms that involve signal detection, source monitoring or attribution processes, alone or in combination, have helped to conceptualise hallucinations in cognitive terms (David 2004) and probabilistic reasoning plays some role in delusions (Gilleen & David 2005; Freeman 2007). Thought disorder does appear to be related to semantic processes and abnormal syntax (see Language and schizophrenia: the problem of 'thought disorder', earlier). Negative or deficit symptoms map more easily onto those deficits familiar in neurologically damaged patients. Lack of motivation, motor slowing, loss of initiative and affective flattening may all be seen in neurological patients, particularly those with frontal–striatal dysfunction, and the corresponding neuropsychological tests usually reflect these impairments (for further reading see David & Cutting 1994; Sharma & Harvey 2000). Social cognitive deficits are of topical interest and it has been proposed that the inability to infer correctly the beliefs, feelings and intentions of others (to have a 'theory of [other] minds') may underlie paranoia as well as inappropriate social behaviours (Frith 1992; Gilleen & David 2005).

Neuropsychological function has been related to various indices of outcome and predictors of rehabilitation success. Indeed, such functioning is a much stronger predictor of global outcome than symptoms. In a thorough review of the literature, Green (1996) and Green *et al.* (2000) concluded that the most consistent finding was that verbal memory was associated with all types of functional outcome so that deficits in this function could limit the level of outcome. Vigilance was related to social problem-solving and skill acquisition while card sorting predicted functioning in the community.

Structural brain imaging

Pathology at the microscopic level is still held up as the defining characteristic of a disease. The application of neuropathology to schizophrenia is reviewed below but its influence on the efforts to understand schizophrenia as a brain disease has recently been overshadowed by *in vivo* neuroimaging, especially MRI. The reasons are obvious: high-level anatomical information can be gleaned from any and all types of patient; samples can be studied that begin to meet epidemiological standards in terms of representativeness and lack of

bias; associations with relevant aetiological factors such as family history, treatment response and phase of illness can all be studied systematically without the need to wait for death and to contend with post-mortem artefacts.

Studies of structural neuroimaging in schizophrenia have parallels with neuropsychology. Quantitative reviews of studies using CT (van Horn & McManus 1992) show clear evidence for generalised loss of tissue (large ventricles and smaller cortical thickness). The body of work relating to structural MRI is now vast and has been subjected to several meta-analyses. These studies, in demonstrating and indeed quantifying consistently observed effects, will inevitably downgrade findings relating to specific brain structures in individual studies. Hence it remains possible that a particular neuroanatomical structure (or network of structures) deemed key to schizophrenia would nevertheless, because of its size, location or difficulties in measurement, be submerged among the larger effect sizes highlighted by meta-analytic reviews.

The most striking finding from both CT and MRI is the increase in ventricular size, a 40% increase being the median value reported in a review of volumetric MRI studies by Lawrie and Abukmeil (1998). Nevertheless, the range of values in schizophrenia overlaps considerably with the normal population so this finding has little clinical utility. The same reviewers calculated that the average loss of brain tissue was a mere 3%, with an effect size (i.e. units of standard deviation) of 0.26. If there is a region that seems to attract more tissue loss than the brain as a whole it is the temporal lobes, with around 8% loss on average in the same review. A more sophisticated analytic approach was taken by Wright *et al.* (2000) in their summation of 58 MRI studies involving 1588 patients with schizophrenia in total. The overall loss of brain volume was 2% and the overall increase in ventricular volume was 26%, mostly accounted for by increase in the body of the lateral ventricles. Medial temporal structures stood out from the rest, with the amygdalae, hippocampi and parahippocampi down by about 6% on both sides; however, this was equivalent to effect sizes (for hippocampus and parahippocampus) of between 0.4 and 0.69, in the moderate range.

The origin of these changes has been illuminated by application of MRI to monozygotic twins discordant for schizophrenia (Suddath *et al.* 1990). As well as having larger ventricles, affected twins had smaller temporal lobes and hippocampi than their co-twins. This compelling work confirmed the association between medial temporal volume loss and the schizophrenia phenotype as well as implying a necessary role for non-genetic factors, obstetric complications being a prime suspect (Dalman *et al.* 2001; Thomas *et al.* 2001; Cannon *et al.* 2002). Subsequent research has shown that unaffected relatives of people with schizophrenia tend to have larger ventricles than non-related controls.

The frontal lobes, despite their obvious functional relevance to schizophrenia, do not show quite the same level

of structural loss, with a mean reduction effect size of 0.36 in a meta-analysis of 22 structural imaging studies (Zakzanis & Heinrichs 1999). Most studies have shown that grey matter takes the brunt of volume changes (Zipursky *et al.* 1992), although this may be partly due to the difficulty in defining white matter tracts reliably enough for volumetric measurement. Large white matter tracts such as the corpus callosum are easy to define, especially in the sagittal plane. This has been shown to be reduced in size in a small meta-analysis (Woodruff *et al.* 1995). Voxel-based methods of analysis avoid the difficulty (and tedium) of tracing around predetermined anatomical regions and are increasingly being employed in structural neuroimaging research. First, each subject's volumetric dataset must be transformed into a standard space and then an average brain volume for one group may be compared (by computer), voxel by voxel, with another. When used in schizophrenia, both white and grey matter regions (medial temporal lobe again, plus insula and prefrontal regions) may be identified as having reduced density, which probably translates to reduced volume (Shapleske *et al.* 2002; Honea *et al.* 2005) (Fig. 2.2: see also Plate 2.2).

In contrast to the repeated finding of reduced cerebral volume, the striatum (particularly the caudate) has been found to be increased in size. This has been attributed to treatment with conventional neuroleptic drugs.

Associations with regional brain pathology

Neurologist Fred Plum (1972) was led to make the memorable remark that 'schizophrenia is the graveyard of neuropathologists'. Now there has been an upsurge of interest in neuropathology, fuelled in part by the findings from neuroimaging and molecular biology (Harrison 1999; Harrison & Weinberger 2005). Plum's remark has been interpreted in several ways: first as a warning to pathologists to steer clear of schizophrenia if they wish their careers to survive, but second that the brain in schizophrenia is like a graveyard, in the sense that all sorts of odd things may be found there – gliosis, infarctions, dysplasias and so on. This latter interpretation is at least empirically supportable. Classical reviews by Davison and Bagley (1969) and Davison (1983) should be consulted as summaries of the rich literature before the era of CT. The coexistence of brain lesions or pathology in people

Fig. 2.2 Brain regions in which significant volume deficits in patients with schizophrenia were reported in voxel-based morphometry studies ($N=15$), by percentage of studies reporting the deficit. In row (a), left and right whole-brain three-dimensional images are overlaid with all regions in which significant volume deficits in patients with schizophrenia were reported. In row (b), a coronal view and an axial three-dimensional image are shown. In row (c), axial views are shown. with schizophrenia raises nosological problems. For example, is any association with brain damage fortuitous or due to the unmasking of a genetic liability to the disorder, or more directly related by way of a causal influence of the brain lesion on the development of the schizophrenia? Harrison (1999) estimated from a thorough review of the neuropathology literature that up to 50% of brains from patients with schizophrenia contain non-specific focal degenerative abnormalities, such as small infarcts and white matter changes. He took these to be mostly if not always coincidental, since they were variable in distribution and nature, and reported as unrelated to the clinical picture occurring well after the onset of symptoms in some cases. Nevertheless, the conclusion emerges that lesions, particularly of the temporal lobes and diencephalon, appear to carry a small but definite risk of increasing the likelihood that a schizophrenia-like illness will develop. This hazard appears to exceed what would be expected in view of the known genetic propensities in the populations concerned. It has not yet been clarified whether such schizophrenias are identical in every respect with the naturally occurring idiopathic disorder, in particular with regard to the course followed. Phenomenologically, however, they appear to be indistinguishable from schizophrenias occurring in the absence of brain disease (Table 2.1).

Irrespective of such nosological refinements, the striking fact appears to be that psychotic illnesses with the major features of schizophrenia may coexist with cerebral lesions and may be generated in some fashion by them. The acute and

chronic organic reactions described in Chapter 1 are by no means the exclusive hallmarks of mental disorder occasioned by cerebral dysfunction. The corollary implication is that while in the great majority of schizophrenias no clear-cut brain lesion will be revealed by routine investigation, in some patients there may be identifiable pathology that warrants careful appraisal.

The evidence incriminating the temporal lobes and diencephalon has come from diverse forms of cerebral pathology. That concerning head injuries is described in Chapter 4 (Psychoses), that for cerebral tumours in Chapter 5 (Temporal lobe tumours) and that for epilepsy in Chapter 6 (Post-ictal disorders). While far from satisfactory or entirely conclusive, for the reasons discussed above, the sum total of evidence begins to look impressive. Other clinical evidence has pointed to disease of the basal ganglia as having a special relationship with schizophrenia-like illnesses, for example in Huntington's disease (Chapter 9), Wilson's disease (Chapter 12) and the rare syndrome of idiopathic calcification of the basal ganglia (Chapter 10). Bowman and Lewis (1980) reinforced this association in their analysis of the site of major pathology in a large variety of cerebral disorders liable to show aspects of schizophrenic symptomatology.

It remains puzzling that frontal lesions are not more often incriminated, with the exception of occasional disorders such as metachromatic leucodystrophy (Chapter 14). Occasional anecdotal reports of schizophrenia following frontal damage are therefore of interest.

Table 2.1 Certainty and doubt in schizophrenia neuropathology. (From Harrison 1999.)

<i>Macroscopic findings</i>	
Enlarged lateral and third ventricles	++++
Decreased cortical volume	++++
Above changes present in first-episode patients	+++
Disproportionate volume loss from temporal lobe (including hippocampus)	+++
Decreased thalamic volume	++
Cortical volume loss affects grey rather than white matter	++
Enlarged basal ganglia secondary to antipsychotic medication	+++
<i>Histological findings</i>	
Absence of gliosis as an intrinsic feature	+++
Smaller cortical and hippocampal neurones	+++
Fewer neurones in dorsal thalamus	+++
Reduced synaptic and dendritic markers in hippocampus	++
Maldistribution of white matter neurones	+
Entorhinal cortex dysplasia	±
Disarray of hippocampal neurones	±
<i>Miscellaneous</i>	
Alzheimer's disease is not commoner in schizophrenia	++++
Pathology interacts with cerebral asymmetries	++

A young man with a family history of depression suffered several episodes of bipolar affective illness over a 2-year period. He then sustained a head injury leading to a left frontal haematoma that necessitated a left frontal lobectomy. Nine months later he developed a classic schizophrenic illness which pursued a chronic course during 6 years' follow-up. A spike-discharging focus was detected 3 years after the injury when he developed epileptic seizures. The authors suggest that the transformation from bipolar affective disorder to schizophrenia, in a patient genetically predisposed to the former, was due to the unusual combination of damage to the left frontal lobe and an excitatory lesion in the left temporal lobe (Pang & Lewis 1996).

A boy sustained a blow to the head in the left frontal parietal region after being knocked from his bicycle by a car at the age of 14 years. There was no fracture, but he was unconscious for 3 or 4 hours and had a lowered level of consciousness for 2 weeks. EEGs at the time and 10 years later were normal. At the age of 16 he presented to psychiatric services following a suicide attempt. He had elaborate delusions of persecution, inappropriate affect and auditory hallucinations. Psychologically he was assessed to be in the bright normal range. An MRI scan carried out at the time of the report, when the patient was in his late twenties, showed generalised ventricular dilatation perhaps greater on the left. There was a family history of psychosis in a maternal cousin but no history of obstetric or perinatal complications. The patient responded to standard treatment (O'Callaghan *et al.* 1988).

A whole range of abnormalities not listed in Table 2.1 may also be found in the brains of people with psychotic disorder, namely those of developmental origin. These include agenesis of the corpus callosum (David *et al.* 1993), cavum septum pellucidum, aqueduct stenosis, arachnoid cysts, and so on (Shenton *et al.* 2001). Some of these would undoubtedly have gone unnoticed were it not for the widespread use of MRI. In clinical settings these disorders sometimes make atypical features of the patient's presentation more comprehensible, such as mild learning difficulty and motor clumsiness or minor physical anomalies. Anecdotally, such anomalies seem to confer a degree of treatment resistance. Statements on the aetiological relevance to schizophrenia requires a ratio to be calculated of the true rate of the abnormality in question in a representative sample of patients against that in the general population. We are beginning to see sufficient MRI research using 'healthy' or near-healthy controls to come up with just such figures. It turns out that of 1000 people, including some elderly, who had volunteered to be controls in

various research projects in the USA, 18% had abnormal MRI scans, although in just under 3% was this deemed to require a referral (Katzman *et al.* 1999). In some other surveys, confined to younger people, even higher levels of abnormalities have been reported. For example in a study of 98 controls, 152 with first-episode psychoses and 90 with chronic schizophrenia, 24%, 22% and 50% had abnormal MR scans, respectively, as judged by a radiologist blind to diagnosis (Lubman *et al.* 2002). Apart from possible evidence of demyelination, infarction, trauma, focal atrophy and white matter hyperintensities (see Chapter 3, White matter hyperintensities), developmental anomalies such as cerebellar ectopia, cavum septum pellucidum, pineal cysts and hamartomas were seen. Again, few required further investigation. Taking these findings together with numerous case reports, it is very likely that such abnormalities are more common in schizophrenia but only account for a small minority of cases. This may be taken as general evidence consistent with the view that disruption in neurodevelopment is a key aspect if not an essential part of the disorder.

While the widespread application of CT and MRI has uncovered cases of brain pathology that might otherwise have been missed, a thorough and systematic medical review will also reveal a small number of cases in whom a systemic disease may be of aetiological relevance. A cohort of 268 first-episode schizophrenia cases investigated by Johnstone *et al.* (1987) produced 15 patients (<6%) with relevant organic disease. These included three cases of syphilis, two of sarcoidosis, and one each of carcinoma of the lung, autoimmune multisystem disease, cerebral cysticercosis and thyroid disease. Substance abuse and previous head injury accounted for the rest.

Neuropathology

A detailed knowledge of the microscopic pathology in the brains of people with schizophrenia is beyond the scope of this book. For a summary of the current state of the art, it would be hard to better Harrison's comprehensive and accessible review (Harrison 1999). He concludes that the best explanation for the reduction in cerebral volume discussed above is reduced neuropil and neuronal size, rather than a loss of neurones. Such morphometric changes are, according to Harrison, suggestive of alterations in synaptic, dendritic and axonal organisation, a view supported by immunocytochemical and ultrastructural findings. Other cytoarchitectural features purported to be more frequent in schizophrenia, such as entorhinal cortex heterotopias and hippocampal neuronal disarray, remain to be confirmed. Importantly, Harrison does not view gliosis as an intrinsic feature, the implication of this being that the disordered brain in schizophrenia is not a response to an acquired insult or disease process as usually understood but rather it supports the hypothesis that schizophrenia is a disorder of prenatal neurodevelopment, and in this respect is quite unlike Alzheimer's disease

for example. In another invaluable summary of this rapidly evolving field, Harrison and Weinberger (2005) summarise evidence linking neuropathology with the identification of several putative susceptibility genes (including neuregulin, dysbindin, *COMT*, *DISC1*, *RGS4*, *GRM3* and *G72*). The authors speculate that these genes may all converge functionally on schizophrenia risk via an influence on synaptic plasticity and the development and stabilisation of cortical microcircuitry. In a further attempt at integration, the authors try to link these findings with the known neurochemistry of schizophrenia and conclude that NMDA receptor-mediated glutamate transmission may be especially implicated, along with of course dopamine and possibly γ -aminobutyric acid (GABA) signalling (Table 2.2).

Functional brain imaging

Functional imaging studies effectively took origin from Ingvar and Franzen's (1974) demonstration of diminished cerebral blood flow to frontal regions in older chronic schizophrenic patients. Subsequent PET studies have given variable results, as reviewed by Bench *et al.* (1990) and Buchsbaum (1990), seemingly due to variations in technique and differences in the populations investigated. Nevertheless, most reports have shown lower metabolism in the frontal and temporal regions and basal ganglia than in posterior brain areas. With further experience, however, such hypometabolism appears to lack specificity in that it may also be seen in some degree in patients with depressive illness (see Executive (frontal lobe) syndromes, earlier). Weinberger *et al.*

(1991) concluded that in all studies which have used cognitive tasks demanding prefrontal activation, schizophrenia patients have tended to show a 'hypofrontal' pattern as measured by cerebral blood flow or glucose utilisation. This provides a tempting explanation for such common symptoms as affective blunting and impaired volition. Taking this further, Frith (1995) points out, for example, that 'self-monitoring' depends on a tight correspondence between anterior brain regions concerned with voluntary motor output and posterior regions concerned with the relevant sensory inputs. When normal subjects generate words there is an increase in blood flow to the dorsolateral prefrontal cortex and an associated decrease in the superior temporal cortex. In schizophrenic patients performing the same task, the dorsolateral prefrontal cortex increase was not associated with decreases in the left superior temporal cortex, implying a lack of connectivity between these two brain areas.

Despite the elegance of much functional MRI research in human subjects, its ability to reveal previously hidden truths about schizophrenia is limited. This stems from the problem in interpreting reduced activation in the light of virtually universally poorer performance. This is especially relevant to functional imaging of prefrontal deficits. When performance is equated, unusual patterns of activation may be seen, such as hyperfrontality, one interpretation being that patients are having to 'work harder' to produce adequate performance. Many researchers have grappled with this problem. Lahti *et al.* (2001) examined activation in deficit and non-deficit patients and showed that overall levels of activation

Table 2.2 Schizophrenia susceptibility genes and the strength of evidence in four domains. (From Harrison & Weinberger 2005.)

Gene	Locus	Strength of evidence (0 to +++)* for			
		Association with schizophrenia	Linkage to gene locus	Biological plausibility	Altered expression in schizophrenia
<i>COMT</i>	22q11	++++	++++	++++	Yes, +

<i>Akt1</i>	14q22-32	+	+	++	Yes, ++

Note: Ratings are of course subjective and transient.

*Based on sample sizes and numbers of replications, not the magnitude of the relative risk; +++ is equivalent to at least three positive independent studies.

were similar between the patient groups and healthy controls on a control sensory motor task, but that only deficit patients failed to activate right middle frontal cortex in relation to a decision task. Cannon *et al.* (2005) made use of a visuospatial working memory task and variable memory load. It was the need to manipulate the visual material in mind that uncovered the patients' failure to increase activation in the dorsolateral prefrontal cortex and this was reflected in a falling off in performance.

Interesting attempts have also been made to explore differences on neuroimaging between schizophrenic patients with and without persistent auditory hallucinations. McGuire *et al.* (1993) obtained clear-cut results by arranging for each patient to serve as his own control, carrying out hexamethylpropyleneamine oxine (HMPAO)-SPECT scans (Chapter 3) first in the presence of ongoing auditory verbal hallucinations, then again some weeks later when these had largely resolved. On each occasion the patient was asked to signal the presence or absence of hallucinations immediately prior to the injection of HMPAO. Increased blood flow was demonstrated in Broca's area during the occurrence of hallucinations, i.e. the area that has been implicated in the subvocal rehearsal of inner speech (Paulesu *et al.* 1993). Such a finding supports the idea that hallucinations arise from the patient's failure to monitor his own thoughts and 'inner speech', which is therefore regarded as alien and perceived as emanating from others.

In a further study, schizophrenic patients liable to auditory verbal hallucinations were compared with those who were not, even though hallucinations were not occurring at the time of testing (McGuire *et al.* 1995). ^{15}O -PET scans were carried out while the subject imagined sentences being spoken in another person's voice. In normal subjects this task is associated with increased activity in such areas as the left inferior frontal gyrus, the supplementary motor area and the left temporal cortex (McGuire *et al.* 1996). Patients prone to hallucinations showed the expected increase in frontal activity, but reductions rather than increases in the supplementary motor area and left temporal regions. Thus it appeared that a predisposition to auditory verbal hallucinations was reflected in aberrant connectivity between the areas concerned with the generation and monitoring of inner speech.

Functional MRI (see Chapter 3) has also been used to explore the cerebral correlates of auditory verbal hallucinations (David *et al.* 1996). Images were obtained during periods of auditory stimulation (speech) and visual stimulation (flashing lights), both when the patient was hallucinating and when he was not. Activation to visual stimulation occurred in the visual cortex irrespective of the presence or absence of auditory hallucinations, whereas temporal lobe activation to auditory stimulation was almost completely suppressed while hallucinations were in progress. David *et al.* interpret this as reflecting physiological competition

for a common neural substrate, normally activated by speech, by the ongoing verbal hallucinations. A similar explanation seems to apply to visual hallucinations (ffytche *et al.* 1998). There have now been over a dozen studies that have tried to 'capture' auditory hallucinations using fMRI. Activity in the superior temporal lobe has been the predominant finding, although left inferior frontal areas also emerge frequently (David 2004).

Hemispheric differences

A separate but perhaps complementary strand to the picture concerns evidence that aspects of cerebral dominance may bear a special relationship to schizophrenia. Historically, the schizophrenia-like psychoses seen with epilepsy tended to be associated with foci in the left hemisphere. Furthermore, neuropathological and neuroimaging investigations have drawn particular attention to changes in the left temporal lobe in the generality of schizophrenias. The prevalence of non-right-handedness in schizophrenia may be taken as further support for the left hemisphere hypothesis or more general evidence in favour of subtle maldevelopment. In neurological terms a lack of cerebral asymmetry has been noted and efforts have been made to capture this completely in terms of 'torque' or radius of gyration. Crow has inferred from this a more fundamental disturbance in laterality and language development which, along with other evidence from wide-ranging sources, he posits to be the basis of schizophrenia psychopathology and which he believes may be related to the speciation of *Homo sapiens* (Crow 2000).

Neurodevelopmental models

A convincing account of a cerebral basis to schizophrenia must try to encompass a number of clinical observations: genetic liability to the disorder, a tendency to appear in adolescence or early adult life, response to certain medications, and distinct associations in certain cases with pathology affecting the temporal lobes and limbic areas. Other findings almost as firm also need to be taken into account: 'season of birth effects' with an excess during the late winter and early spring months, vulnerability to life events and to 'expressed emotion', the presence of antecedent impairments from childhood onwards (Jones *et al.* 1994), and a host of tantalising relationships with aspects of cerebral laterality.

The neurodevelopmental theory of schizophrenia has gained prominence in the field and is argued persuasively by a number of authorities (Weinberger 1987, 1995; Murray *et al.* 1988; Allin and Murray 2002). It encompasses both genetic and environmental factors as having a causal relationship to the disease. Though not applicable in every case, the theory claims to account for a sizeable proportion of patients, particularly those with early onset of the illness and prominent negative symptoms.

It is suggested that many schizophrenic subjects harbour 'brain lesions', especially in the limbic system and frontal cortex, that have originated very early in life extending back even to the intrauterine period. Such lesions, which are of a subtle nature, predispose the affected person to develop schizophrenia later. They may be the product of genetic influences controlling early brain growth, infection, immune disorder, complications of pregnancy or abnormal patterns of neuronal migration. These last may be occasioned by damage to the fetus during pregnancy or may themselves be inherited directly. Important variables with respect to the risk of developing schizophrenia are likely to include the site and timing of the disturbances, and the presence or absence of a genetic predisposition to the disorder.

There are precedents for such a situation in both animal experimental work and humans (Weinberger 1987). Thus a lesion of the dorsolateral prefrontal cortex does not markedly affect the infant monkey's behaviour, but disrupts performance on delayed response tasks in adulthood. Similarly, perinatal hypoxia may lead to cerebral palsy in infancy but to athetosis and epilepsy some years later. Brain myelination is also known to continue well into postnatal life, particularly in areas such as the corpus callosum and the prefrontal cortex. Weinberger (1987) stresses that the dorsolateral prefrontal cortex is one of the last brain areas to myelinate, this continuing well into the second and third decades of life. In his model the declaration of symptoms may depend on the maturing of cortical-subcortical relationships.

Sex differences with regard to schizophrenia can be accommodated within the neurodevelopmental model. There is consistent evidence that the onset of the illness is earlier in males than females, and that males show poorer premorbid adjustment and tend to have a poorer outcome (Castle & Murray 1991). This accords with the evidence from neuroimaging and neuropathology that the male schizophrenic brain is more often abnormal than the female. Moreover, neurodevelopmental disorders are generally commoner in boys than girls, as with developmental dyslexia and autism, perhaps as a result of slower maturation or greater lateralisation of function that renders compensation for damage less successful.

Clinical Assessment

Anthony S. David

Institute of Psychiatry, King's College, London

The assessment of patients with organic psychiatric disorder follows the time-honoured principles of clinical practice generally. It is sometimes a time-consuming process, requiring a good deal of patience and persistence. A careful history is essential, the mental state must be systematically examined, and a thorough physical examination will be required as well. The picture will then often remain incomplete without evaluation by a clinical psychologist with neuropsychology skills and the undertaking of certain ancillary investigations. A period of observation in hospital in a specialised unit can do much to clarify the situation when the diagnosis is unclear, but may not be accessible. Similarly, direct observation of the patient's living circumstances can be highly illuminating. In many cases, the initial contact with the patient will merely serve to establish the major probabilities in diagnosis and allow more detailed planning for further enquiries.

No attempt is made in the present chapter to outline a comprehensive schema for psychiatric history-taking or examination. This is dealt with in textbooks of general psychiatry and related publications (Goldberg & Murray 2006). The purpose here is to focus on those aspects of clinical enquiry which assume particular importance when one suspects an organic disease process in the genesis of the patient's mental symptoms. The value of certain psychometric tests and other investigatory procedures is also discussed.

History-taking

The difference between a good neuropsychiatrist and a mediocre one is a good history, which must include an informant interview and information on previous medical contact (the 'old notes'). And be aware that a 'poor historian' is the description of someone who takes a poor history rather than one who gives it.

If the history is equivocal, certain features on examination usually soon indicate when there is likely to be an organic

basis for the disturbance. The main task thereafter is to refine the diagnosis by seeking to determine the nature of the pathological process. It is only in a minority of patients, albeit a vitally important group, that the presentation may be misleading, namely in the very early case or in cases with an abundance of 'functional' psychiatric features.

Time spent in obtaining a detailed history is almost always rewarded, and may yield more important leads to the correct diagnosis than a host of investigations. Certainly it will indicate what investigations, if any, need to be pursued. Moreover, the patient's account and his behaviour during interview will provide a wealth of information about his mental state and the intactness or otherwise of cognitive functions.

Statements derived from the patient alone frequently prove misleading, with regard to both the gravity of the symptoms and the time course of their evolution. This is clearly so when the patient is confused or suffering from obvious memory impairment, but can be equally important in other situations. The changes occasioned by brain damage can be hard for the patient to evaluate subjectively, even when insight is largely retained. Certainly, when asked to judge whether memory or other difficulties are worsening or improving, he will often seize on some recent instance that may have more to do with chance and circumstance than with the course of the clinical condition. In many cases there will be genuine loss of insight, and sometimes a desire to conceal from himself and from others that intellectual functions are failing. Sometimes, too, the early changes will be of a type more obvious to outsiders than to the patient himself: changes in mood, enthusiasms, habitual activities and attitudes. Such matters obviously require the detailed testimony of someone who has known the patient intimately throughout the evolution of the disorder.

Abnormalities are likely to include such matters as disordered behaviour, and disturbances of mood, memory and subjective experience. Physical symptoms will also often

figure prominently. The full range of complaints and apparent defects of functioning must be carefully explored, with readiness to search beneath the immediately presenting picture. Physical symptoms may have come to serve as the focus of attention for the patient and his relatives, and the true extent of mental abnormalities may only be revealed by specific enquiry. On the other hand the physical components should not be lightly brushed aside; in particular complaints of headache, malaise or generalised weakness must not be underestimated. When there is a problem of differential diagnosis between organic and non-organic mental illness, it will be necessary to preserve a delicate balance in the enquiries until information begins to tip the balance in one direction or the other (Lishman 1992).

Particular attention must always be paid to the mode of onset of the disorder, the duration of symptoms and the way they have progressed. Where developments have been insidious the onset is often dated very imprecisely, even by relatives, with some striking incident serving as a screen for much that went before. Systematic enquiry about the level of functioning prior to the alleged onset can then be useful – behaviour on a previous holiday or at Christmas time for example – and serve to remind informants of the earlier evidence of disorder.

Enquiry should always be made for fluctuations in behaviour or changes that have been observed from one situation to another. Nocturnal worsening is an important indicator of minor degrees of clouding of consciousness. Behaviour which is relatively intact in the restricted field of domestic activities may be dramatically changed when new experiences need to be confronted. Episodic abnormal behaviour of sudden onset and ending will raise the suspicion of an epileptic component.

Other salient matters which deserve specific enquiry are outlined in Chapter 1 where differential diagnosis is discussed. These include not only features among the presenting symptoms, but also antecedent conditions such as head injury, alcoholism or drug abuse. A long list of medically unexplained symptoms cropping up periodically over a number of years, sometimes known only to the patient's general practitioner, is essential in formulating a diagnosis around somatisation or conversion. Tactful and careful enquiry may need to be made about sexual practices if any suspicion of AIDS arises. Any recent physical illness must be noted, or medications recently prescribed, or conditions predisposing to anoxia such as cardiac failure, respiratory inadequacy or the recent administration of an anaesthetic. Any history of dysphasia, paresis, fits or other transitory neurological disturbances must be ascertained.

It is perhaps worth emphasising that the formal psychiatric history remains important even when the presenting complaints have a markedly organic flavour. Where the question arises of a differential diagnosis between organic and non-organic mental illness, all parts of the standard psy-

chiatric enquiry will need to be completed. Previous reactions to stress, and symptoms observed during previous episodes of ill health, may help to clarify the significance of the present clinical features. Of course when there is abundant evidence of a cerebral pathological process, some parts of the formal psychiatric history will be redundant. However, there is still a need to know about premorbid patterns of functioning, special vulnerabilities and details of the patient's social and family setting. Such information may throw light on the content of the illness and on special factors that will need to be borne in mind in management. Knowledge of the level achieved in education and at work can similarly be valuable in assessing present evidence of intellectual decline.

Physical examination

The more one suspects an organic basis for the patient's mental condition, the more important will be the physical examination. Often it is the latter that yields decisive information about the precise aetiology and the treatment required. In practice the dichotomy between the physical and the mental examination can tend to melt away, with each providing essential leads to the other. This is particularly evident in the examination of higher mental functions, where the neurological examination overlaps with the detailed assessment of cognitive status.

Special attention will usually need to be devoted to the neurological system, but other systems can be just as crucially important. Johnson (1968) found that among 250 consecutive admissions to a psychiatric hospital, 12% had some physical illness that was an important aetiological factor in the presenting mental disorder. The majority were diagnosable by routine physical examination and had been missed prior to admission. Among his examples were cases of myxoedema, neurosyphilis, cerebral anoxia due to cardiac failure, chest infections, anaemia, liver failure, carcinoma and cerebral vascular disease. In addition many other physical disorders were discovered that did not contribute directly to the presenting clinical picture. Even higher rates are seen in elderly patients admitted to psychiatric receiving wards. Koran *et al.* (1989), in a thorough evaluation of patients in the Californian mental health system, identified an important physical disease in almost 40% of cases. This was judged to be causal in 6% and to exacerbate the mental disorder in 9%. Relevant conditions included organic brain syndrome, epilepsy, migraine, head injury, diabetes, and thyroid and parathyroid disorders. One-sixth of the causal illnesses had been overlooked, also more than half of those which were exacerbating the picture. Some of the principal physical signs that must be sought with care are described in the following text. There are several reasons why physical and psychiatric illnesses may coincide (Box 3.1).

Box 3.1 Reasons why psychiatric patients may have physical illnesses

- 1 Chance association
- 2 The physical illness is responsible for the psychiatric disorder
 - (a) Any disease affecting the central nervous system
 - (b) Treatment for the physical illness causes psychiatric side effects, e.g. steroids, dopamine agonists
- 3 The psychiatric disorder and the physical illness are both associated with a common factor, e.g. alcohol dependence causing amnesia and neuropathy
- 4 The psychiatric disorder has increased the risk of physical illness
 - (a) By self-neglect, poor diet, failure to comply with medical advice or, more directly, because of unusual beliefs leading to highly abnormal or restrictive diets, exposure to toxins, self-injury, risk-taking behaviours
 - (b) Treatment for the psychiatric disorder causing adverse physical (including neurological) effects, e.g. parkinsonism and tardive dyskinesia following antipsychotic medication
- 5 The physical complaint is related to psychological factors, e.g. biological symptoms of depression, abnormal illness behaviour

It is important, especially in the neurological examination, to interpret abnormal findings in relation to the total clinical picture. Among the elderly in particular, isolated neurological abnormalities can be without significance. Absent vibration sense, mild tremors, sluggish and irregular pupils, isolated abnormalities of tendon reflexes or a doubtfully positive plantar response may lack diagnostic significance, or be related to minor pathology without relevance to the present problem. On the other hand, when viewed against the total picture these can be just the features which lead eventually to the true diagnosis.

Gross neurological abnormalities will rarely be encountered in patients with diffuse cerebral impairment, but certain less striking features should be carefully observed. Some of these are not widely appreciated and can be important in raising suspicion of a degenerative brain process. Lack of manual precision, motor impersistence and perseveration of motor acts may emerge clearly in the course of neurological testing. A clumsy graceless walk or minor unsteadiness may betray cerebral pathology, even in the absence of definite pyramidal, extrapyramidal or cerebellar signs. This may be striking once attention has been directed towards it. In patients suspected of cerebral vascular disease, special attention should be paid to swallowing, speech and the jaw jerk as indicators of early pseudobulbar palsy. A wide-based gait has been stressed as an early indicator of normal-pressure hydrocephalus (see Chapter 9, Examination). Minor parkinsonian features, such as a stooping posture or lack of associated arm movements on walking, may also be noticed in diffuse cerebral disease. Table 3.1 sum-

marises important neurological signs that might be especially useful in the diagnosis of dementing conditions.

Neurological soft signs

As well as these general observations and the conventional neurological examination, a number of other signs may be elicited that may betray subtle neurological dysfunction. These include the so-called soft neurological signs, which comprise integrative sensory functions such as sensory extinction and graphaesthesia, motor sequencing acts such as the first-edge-palm test, and the primitive reflexes such as the pout, snout, grasp and palmomental (unilateral contraction of the muscles of the chin producing a wince-like movement when the thenar eminence of the ipsilateral hand is stroked briskly). Mirror movements (movement provoked in the one hand during a complex unimanual action in the other) may be observed. These signs have low specificity, being found in patients with a variety of diffuse neurological disorders and dementias as well as developmental disorders and the psychoses, not to mention a small proportion of healthy subjects, especially the elderly; they have been shown to correlate with negative symptoms and cognitive impairments in schizophrenia (Bombin *et al.* 2005). Nevertheless, a prominent grasp reflex in a young adult with a history of personality change for example would raise suspicion of a frontal lobe syndrome.

The mental state

The evaluation of mental state provides a cross-sectional view that supplements the longitudinal view of the illness derived from the history. It also adds decisive information of its own. It is essential to realise that key features such as memory impairment may have to be sought diligently if they are to be properly displayed.

There are obviously certain aspects of the mental state which are of especial importance in organic psychiatric disease, and these are described in some detail below. In particular, the correct evaluation of cognitive functions is often central to the identification of cerebral pathology. However, too early or exclusive a preoccupation with the assessment of cognitive functions can be a mistake, and stands to leave much valuable information uncharted. Shortcuts should be avoided, the aim being always a systematic and comprehensive examination of the full range of mental phenomena. Often, for example, it is uncertain how much of the picture may be explained on the basis of non-organic rather than organic mental disturbance, and such a differentiation requires careful assessment of all aspects of the mental state. Even when cerebral pathology is abundantly obvious, it is still necessary to be thoroughly aware of the patient's affective state, the nature of his interpersonal reactions and the content of his subjective experiences. The emphasis in the following sections on certain aspects should therefore not

Table 3.1 Abnormal neurological signs and their significance in dementia. (From Cooper & Greene 2005 with permission of BMJ Publishing Group Ltd.)

Physical sign	Seen in
Ataxia	Paraneoplastic disease, cerebellar tumour, Whipple's disease, Creutzfeldt–Jakob disease, AIDS dementia complex, spinocerebellar ataxia, Wernicke–Korsakoff syndrome, Hallervorden–Spatz syndrome, ornithine transcarbamylase deficiency, Niemann–Pick disease, mitochondrial disorders, adrenoleucodystrophy, neurodegeneration with brain iron accumulation, lead poisoning
Involuntary movements	Huntington's disease, inherited metabolic disorders including Wilson's disease, Creutzfeldt–Jakob disease, corticobasal degeneration, systemic lupus erythematosus, Whipple's disease, Hallervorden–Spatz syndrome, Lesch–Nyhan syndrome
Myoclonus	Post-anoxia, Creutzfeldt–Jakob disease, Alzheimer's disease, subacute sclerosing panencephalitis, myoclonic epilepsies, Hashimoto's encephalopathy, dementia with Lewy bodies, corticobasal degeneration (CBD)
Extrapyramidal signs	Dementia with Lewy bodies, Parkinson's disease, progressive supranuclear palsy, vascular dementia, frontotemporal dementia, Creutzfeldt–Jakob disease, Wilson's disease, Huntington's disease, dentato-rubro-pallido-luysian atrophy, neuroacanthocytosis, cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy (CADASIL), Niemann–Pick disease, mitochondrial disorders, neurodegeneration with brain iron accumulation
Pyramidal signs	Motor neurone disease, Creutzfeldt–Jakob disease, CBD, vitamin B ₁₂ deficiency, multiple sclerosis, spinocerebellar ataxia, multisystem atrophy, hydrocephalus, Alzheimer's disease, Hallervorden–Spatz syndrome, CADASIL, mitochondrial disorders, adrenoleucodystrophy, frontotemporal dementia
Optic disc pallor	Multiple sclerosis, vitamin B ₁₂ deficiency
Papilloedema	Tumour, subdural haematoma, hydrocephalus
Cortical blindness	Vascular disease, Alzheimer's disease, Creutzfeldt–Jakob disease
Anosmia	Subfrontal meningioma, head injury, Alzheimer's disease, Parkinson's disease, Huntington's disease
Abnormal eye movements	Progressive supranuclear palsy, Wernicke–Korsakoff syndrome, Whipple's disease, corticobasal degeneration, mitochondrial cytopathies, cerebellar tumours, causes of raised intracranial pressure, Creutzfeldt–Jakob disease, mitochondrial disorders, Huntington's disease, Niemann–Pick disease type C
Other cranial nerve signs	Sarcoidosis, tumours, neoplasia, tuberculous meningitis
Alien hand	Corticobasal degeneration
Visual field defect	Tumour, vascular disease, Creutzfeldt–Jakob disease
Pupillary abnormalities (Argyll Robertson pupil)	Neurosyphilis
Peripheral neuropathy	Vitamin B ₁₂ deficiency, paraneoplastic disorders, neuroacanthocytosis, spinocerebellar ataxia, Hallervorden–Spatz syndrome, adrenoleucodystrophy, neurodegeneration with brain iron accumulation, lead poisoning, systemic lupus erythematosus
Early onset incontinence	Tumour, hydrocephalus, progressive supranuclear palsy
Bulbar features	Frontal dementia (motor neurone disease)
Fasciculations	Frontal dementia (motor neurone disease), rarely Creutzfeldt–Jakob disease
Seizures	Vasculitis, neoplasia, primary angiitis of the nervous system, limbic encephalitis, AIDS dementia complex, neurosyphilis, subacute sclerosing panencephalitis, Hashimoto's encephalopathy
Grimacing facial expression	Wilson's disease

be taken to imply that other areas are necessarily of minor importance.

The mental state observed at interview must be evaluated against background information from others who have observed the patient in real-life situations. The interview has its own importance in allowing a systematic exploration of relevant areas of function, but is necessarily restricted in scope and is in many ways an artificial situation. For this reason admission to hospital for a period of observation often adds greatly to the assessment, although this is increasingly difficult to organise within modern community-orientated psychiatry services. Nurses' reports of behaviour in the ward, interactions with others and variability during the day can yield crucial information. Occupational therapy can provide the best setting of all when it comes to observing the detailed nature of the patient's difficulties over everyday tasks.

Appearance and general behaviour

Certain features obvious at a glance may raise suspicion of an organic basis for mental symptoms. Any evidence of physical ill health should be noted: pallor, loss of weight or indications of physical weakness. The facies can be very important: a certain laxness of the muscles of the lower face and lack of emotional play about the features can suggest a cerebral degenerative process in the absence of depression. Movements may be slow, sparse or tremulous. The appearance may be older than expected for the patient's age, or standards of self-care and general tidiness may be poor. A lapse of standards that cannot readily be explained on the basis of severe emotional disturbance can be a sensitive pointer to cerebral pathology.

Features which should be noted in the course of conversation include slowness, hesitancy, perseverative tendencies and defective uptake or grasp. This is the time to note whether the patient is alert and responsive or dull and apathetic, whether he is friendly and cooperative or distant and reserved. The adequacy with which attention can be held, diverted or shifted from one topic to another may be seen to be abnormal. Impulsiveness, disinhibition or blunted sensitivity to social interaction are other relevant features that may emerge during the interview. The patient may be noted to tire unusually quickly with mental effort.

Behaviour in the ward can also be revealing. The patient may prove to be indifferent to events and out of contact with his surroundings, sometimes with variability from one part of the day to another. Impaired awareness of the environment may be manifest in a puzzled expression, aimless wandering, restlessness or repetitive stereotyped behaviour. Responses to various requirements and situations may reveal defects not previously suspected. He may lose his way, misidentify people or betray serious lapses of memory. Interactions with those around may reveal paranoid tendencies, or he may be observed to react to hallucinatory experi-

ences not previously disclosed. Competence over dressing, undressing and matters of hygiene can be assessed. Disordered feeding habits can occasionally reveal the inroads of dementia in a patient with an otherwise well-preserved social manner. Any episode of incontinence will of course be noted, along with the patient's reaction towards it.

Mood

A variety of abnormalities of mood can occur with organic cerebral dysfunction, depending partly on the nature of the cerebral pathology and partly on the premorbid personality. Some forms of reaction are particularly common and immediately raise suspicion.

Clouding of consciousness is often accompanied by an inappropriate placidity and lack of concern, coupled with some degree of disinhibition. The florid hostile or fearful moods of delirium are also characteristic, often changing rapidly from one moment to another. In early dementia a quiet wondering perplexity is often the predominant mood, or emotional lability in which signs of distress resolve as abruptly as they appear.

An empty shallow quality to the emotional display should always raise suspicion of organic cerebral disease, likewise apathy in which there is little discernible emotion, and euphoria in which a mild elevation of mood is unbacked by a true sense of happy elation. Emotional blunting and flattening are other characteristic signs. These classic forms are not invariable, however. Some patients with organic brain damage show heightened and sustained anxiety or marked depressive reactions.

Characteristic emotional responses may emerge when the patient is faced with problems that tax his ability. He may over-react in an anxious aggressive manner, or alternatively become quiet, sullen and withdrawn. Goldstein (1942) described the catastrophic reaction (*katastrophenreaktion*) that can be observed in such circumstances, occasionally without warning but usually heralded by increasing anxiety and tension. The patient looks dazed and starts to fumble. Whereas a moment before he was calm and amiable, he now shows an intense affective response, varying from irritability and temper to outbursts of crying and despair. Autonomic disturbance is seen in the form of flushing, sweating or trembling. He may become evasive where further questions are concerned, or show a sudden aimless restlessness.

Talk and content of thought

The patient's talk, both spontaneously and in response to questions, provides a wealth of important clues. Discursive tendencies may be noted, or minor incoherence, or perseverative and paraphasic errors. Perseveration is a sign of great importance in indicating cerebral pathology; having given a response the patient repeats this inappropriately to subsequent questions, as a consequence of difficulty with shifting his attention. Perseveration must be distinguished from reiteration, in which the patient continually repeats some

word, phrase or question without intervention by the examiner. The formal examination for dysphasic disturbances is considered below (see Chapter 2, Disorders of language and the aphasias).

There may be pressure of talk, which serves as a screen to cover defects. The patient may employ denials or evasions when pressed for details about his history, or try to explain away failures with facile rationalisations. It can be important to push gently beneath a well-preserved social façade in order to determine the true extent of the inroads made by cerebral pathology.

Observation of the content of talk is the chief means of access to the patient's thought processes. A surprising poverty of thought may be revealed, or preoccupation with restricted themes. Associations may be found to be impoverished and reasoning power impaired.

Time should be spent in attempts to get as complete a picture as possible of any pathological ideas, experiences or attitudes that may be present. Paranoid tendencies are common in the presence of intellectual deterioration and ideas of reference may be marked. Delusional ideas may be stamped with certain characteristic features, as already described in Chapter 2.

Perceptual distortions, illusions and hallucinations must be noted. In organic psychiatric disorders these occur chiefly in the visual modality; they tend to be commoner when sensory cues diminish towards nightfall, and may be fleeting and changeable. Feelings of familiarity or unfamiliarity may be intrusive, with depersonalisation, derealisation or *déjà vu*. Body image disorders merit careful assessment.

The patient's attitude to his illness should always be ascertained. He may fail to recognise that he is unwell, deny any disability or take a surprisingly lighthearted view of his case. At the same time he may prove to be fully compliant over examination or admission to hospital. His own explanations for his symptoms should be determined. This alone can give important indications concerning his capacity for making realistic judgements.

Assessment of the cognitive state

The cognitive state examination can be crucial for producing evidence of an organic component in a mental illness. The number of tests and procedures available for assessing cognitive functions is rather bewildering, and it is therefore helpful to acquire a standard routine. This also has value in building up the clinician's experience of the different tests and the meaning to be put on failure in various situations. He can then formulate subjective judgements in cases where the evidence is not clear-cut; such judgements in turn are essential when deciding whether more detailed investigations should be undertaken.

Most of the brief shorthand tests employed by the psychiatrist lack adequate standardisation and validation. Indeed

when their value has been tested they have often, taken individually, proved to be remarkably inefficient in distinguishing between organic and non-organic psychiatric illness. Many prove to be closely related to the patient's educational level and general intelligence, some are markedly affected by increasing age and others by emotional disturbance. Some of the more detailed psychometric procedures elaborated by psychologists are clearly superior for the task of identifying organic psychiatric disorder but are too cumbersome for use in every patient.

Nevertheless, the routine tests available to the clinician have a value of their own. They have the important virtue of throwing a wide net and touching on a number of facets of cognitive function in a reasonably concise manner. In the course of administering them the examiner also obtains numerous indirect clues; the patient's behaviour while attempting the tests, and the nature of his approach, provide important information in themselves. Thus when taken in conjunction with observations gleaned during the interview there is a substantial chance that cerebral impairment will be suspected when it exists. Such suspicions can then be followed up by more decisive means.

The fact that patients with non-organic psychiatric conditions sometimes show impaired performance on the tests is paradoxically of value as well. It is important, for example, to gauge how severely concentration is impaired in depressive illness, or to observe how little impact outside events have made in a patient with severe and sustained anxiety. The routine use of the tests in every patient is therefore seldom a waste of time.

The important matter is to recognise the limitations of the tests and to have a clear strategy for knowing how far to press the cognitive status examination in a given situation. A brief examination is described below for use in every psychiatric patient, and then a more extended battery for use when organic cerebral disease is definitely suspected.

Routine cognitive state examination

Orientation

Orientation for time is assessed by asking the patient to name the day of the week, date, month and year. Minor degrees of temporal disorientation may be identified by asking the patient to estimate the time of day, or to estimate how much time has elapsed since the interview was started. *Impaired appreciation of the flow of time* is sometimes surprisingly revealed and points strongly towards delirium. Orientation for place is assessed by asking the patient to name his present whereabouts and to give the address. Orientation for person is tested simply by asking the patient his name.

Common sense must obviously be used in administering these simple questions. It will usually have become apparent in the course of history-taking if the patient is correctly orientated for place and person and these questions can therefore often be omitted. However, orientation for time is worth

testing in all patients, since this is commonly the first area to suffer in the course of mild impairment of consciousness or intellectual impairment. Latitude will obviously be required in interpreting errors with respect to date; Brotchie *et al.* (1985) showed that errors of a day or more occurred in 29% of healthy elderly subjects when orientation was accurate in other respects. Patients with chronic schizophrenia may underestimate their age (age disorientation) and this error tends to predict wider cognitive impairments. It points to a failure to update personal records with the entrenchment of the disorder and is claimed not to be a mere by-product of institutionalisation (Manschreck *et al.* 2000).

Attention and concentration

Marked difficulties with attention and concentration will usually have become apparent in the course of history-taking and examination. When so, it is important to record qualitative observations in full.

Note deficiencies in the way in which attention is *aroused* or *sustained*, whether the patient is readily *distracted* by extraneous or internal stimuli, and whether *attention fluctuates* from one moment to another. There may be difficulty in *shifting attention* from one topic or frame of reference to another, or attention may be *diffuse* so that it cannot be directed to a particular purpose. Note impairment of ability to *concentrate on a coherent line of thought or reasoning*, or undue readiness with which powers of concentration become *fatigued*.

Brief tests that can be used to record attention and concentration include asking the patient to give the days of the week or months of the year in reverse order; recording and timing his efforts to subtract serial sevens from 100; or asking him to perform other simple tests of mental arithmetic appropriate to his level of intelligence.

The ability to repeat digits forwards and backwards (digit span) provides another useful yardstick. The digits must be delivered in an even tone and at a rate of one per second if accurate comparisons are to be made. A start will usually be made with two or three digits forwards, increasing by one each time until the patient's limit is reached.

Memory

The ability to register, retain and retrieve information should be assessed by two or three simple tests. The patient's capacity for current memorising (new learning) has the most important clinical implications and warrants close attention.

Ask the patient to listen carefully while you tell him a name and address, then ask for its immediate reproduction. Record his answer verbatim, and repeat if necessary when the first response is unsatisfactory. Test retrieval 3–5 minutes later after interposing other cognitive tests, and again record the answer verbatim.

Test ability to repeat a sentence immediately after a single hearing. The sentence should be appropriate to the patient's intellectual level as in the following examples from the Stanford–Binet series.

- Year 13: 'The aeroplane made a careful landing in the space which had been prepared for it'.
- Average adult: 'The red-headed woodpeckers made a terrible fuss as they tried to drive the young away from the nest.'

- Superior adult: 'At the end of the week the newspaper published a complete account of the experiences of the great explorer.'

If suspicion of impairment has arisen, test the number of repetitions necessary for accurate reproduction of the eponymous Babcock sentences: 'One thing a nation must have to become rich and great is a large secure supply of wood' or 'The clouds hung low in the valley and the wind howled among the trees as the men went on through the rain'. Three repetitions of either of these sentences should allow word-perfect reproduction in a patient of average intelligence.

A technique similar to that of Irving *et al.* (1970) may be useful with patients of limited ability or when it is hard to be sure of cooperation. The patient is told he will be given the name of a flower and asked to repeat it ('The flower is – a daffodil – please repeat daffodil'), then a colour ('The colour is – blue – please repeat blue'), then a town ('The town is – Brighton'), and so on. The list may continue with makes of car, days of week, etc., until some six or ten items have been given according to the patient's ability. Recall is tested 3–5 minutes later, first without prompting, then if necessary after giving each category name. This provides the opportunity for testing free recall and cued recall separately, and will sometimes demonstrate good learning ability when other techniques have failed. Perseveration is sometimes clearly displayed on the test, likewise confabulatory tendencies.

Other aspects of memory assessment are necessarily largely subjective. Discrepancies may already have emerged between the patient's account of his illness and that given by informants. *Pay special attention to memory for recent happenings and in particular for the temporal sequence of recent events.* The circumstances surrounding the patient's admission to hospital and happenings in the ward thereafter should be briefly reviewed, since these are matters about which the examiner will have independent knowledge.

Retrieval from the remote past is more difficult to evaluate, but an attempt should be made to judge the adequacy of the patient's account of his earlier life, and to examine this for evidence of gaps or inconsistencies. Care must be taken in doubtful cases to frame questions in such a way that memory for the past is truly tested. Thus the question 'How old were you when you started school?' can produce an easy habitual response and secure a correct reply, whereas 'Can you describe your first day at school?' requires the mobilisation of actual memories.

Record any *selective impairments of memory* which become apparent in the interview for *special incidents, periods or themes* in the patient's life. *Retrograde and anterograde amnesia* must be specified in detail in relation to head injury or epileptic phenomena. Describe any evidence of *confabulation* or *false memories*. Note the patient's attitude to any memory difficulties which he displays.

General information

A brief estimate should be made of the patient's knowledge of current events, and of his ability to handle material from his long-term memory store (utilisation of old knowledge).

Ask about recent items of interest in the news, political, sporting or otherwise, in accordance with the patient's known interests and activities. Ask him to name key personalities: members of the Royal Family, prime ministers, members of the cabinet or well-known television performers. (Clearly such questions will only need to be pursued when reason has emerged to doubt the patient's competence.) In patients who disclaim any interest in political or sporting events, television soap operas can provide a useful vehicle for assessment, providing of course that the examiner is adequately informed about them! Surprisingly detailed knowledge may be forthcoming in patients who appear to be severely impaired.

Ask for the dates of the first and second world wars, and test for knowledge of capitals and countries. In the face of poor responses pursue the patient's general knowledge further by asking for names of cities in England, rivers, etc.

If reason has emerged to suspect a disturbance of abstract thinking, ask the patient to explain the difference between concepts such as 'child' and 'dwarf', 'poverty' and 'misery', 'river' and 'canal', 'lie' and 'mistake', and test ability to give the meaning behind well-known proverbs.

Intelligence

The patient's educational and occupational history, taken in conjunction with his own interests and activities, should allow a rough estimate to be made of the expected level of intelligence. *Any aspects of performance during testing which are at variance with this should be carefully noted.*

Orientation for time and place is closely bound up with current memorising ability and with clarity and coherence of thought. The tests of orientation as described above are nevertheless very useful, and have repeatedly emerged as among the most discriminating features in the mental state examination for distinguishing between organic and non-organic psychiatric disorders. Attention is not a clearly defined concept and overlaps with functions described as alertness, awareness and responsiveness. It is nonetheless widely accepted as a clinically useful concept, with particular relevance to general mental acuity and minor impairment of consciousness. Concentration is a similarly imprecise term, referring to capacity for focusing and sustaining mental activity on the task in hand. Both stand to be markedly affected by preoccupations or abnormalities of mood, and can therefore be disturbed in many forms of psychiatric illness. Equally, however, they can give important indications of clouding of consciousness or general intellectual impairment. It will be noted that simple tests of arithmetic form an integral part of the tests for attention and concentration, and this in itself can be valuable in revealing marked defects in numerical ability. The digit repetition test is included in this section, rather than in the assessment of memory, since it is well established that the immediate memory span is usually normal in amnesic subjects.

The assessment of memory is of the utmost importance, since memory failure is a particularly sensitive indicator of

cerebral dysfunction. It is here that the most decisive evidence of an organic component in the illness will often be obtained. Fortunately for clinical practice, the aspect of memory that is most amenable to careful testing is also the aspect most vulnerable to cerebral dysfunction, namely the capacity for acquiring and retaining new information.

The section on general information extends the evaluation of memory, and at the same time brings added information against which to judge the likelihood of generalised intellectual impairment.

Mini-Mental State Examination

The Mini-Mental State Examination (MMSE) was elaborated by Folstein *et al.* (1975) as a simplified form of the routine cognitive status examination. It has the virtue of brevity, taking only 5–10 minutes to administer, yet test–retest reliability is high and it has been shown to discriminate well between patients with dementia and delirium (Anthony *et al.* 1982). The MMSE is widely used and provides a rough and ready index of cognitive functioning and can be used to track improvements and deterioration.

The first section covers orientation, memory and attention. Memory is tested by noting the number of trials required to learn three object names, then testing recall later. Attention is assessed by the serial subtraction of sevens or by spelling a word backwards. The second section tests ability to name common objects, follow verbal and written commands, write a sentence spontaneously and copy a simple figure (overlapping pentagons). The total score obtainable is 30, scores of less than 24 usually being indicative of cognitive impairment.

There are limitations to the MMSE, such as the relative paucity of memory and general knowledge items and those which tap into frontal-executive functions.

Extended cognitive state examination

The examination described above is adequate for routine psychiatric practice. The abnormalities that emerge will need to be evaluated against the total picture presented by the patient: sometimes they will raise the possibility of organic cerebral disorder, but quite often they will be attributable to factors such as low intelligence, emotional disturbance or psychotic thought disorder. More latitude will then be allowed for failure. However, when they raise a strong suspicion of organic psychiatric illness, more thoroughgoing evaluation will be required.

Some points of caution must be observed before embarking on the extended cognitive state examination.

- 1 The examination can be lengthy and fatigue may produce misleading results; the procedures should not be hurried, and several brief sessions are usually preferable to a single long drawn-out examination.

- 2 The examiner must remain sensitive to the patient's reactions to failure. A particular test must sometimes be set aside

for a while in the interests of sustaining cooperation; tests which are pressed too firmly may provoke ‘catastrophic’ reactions or bewilder the patient to the point where useful information is no longer obtained.

3 The tests must be adapted to the patient’s intelligence and educational level, and to his particular difficulties.

4 It is essential to remain aware that one disability may have repercussions on performance at other tasks. Defective comprehension, for example, will cloud the issue when it comes to testing for dyspraxia. Allowance will need to be made for this in the selection of the tests, the order of their administration and the assessment of results.

Consequently, it is helpful to have a simple routine at the outset which allows the key area of function to be assessed in an abbreviated fashion, before proceeding to lengthier parts of the examination (Box 3.2).

A somewhat more systematic expansion of the MMSE has been proposed and this also serves as a bridge between initial assessment and formal neuropsychological assessment or between an extended clinical neuropsychiatric evaluation. The Addenbrooke’s Cognitive Examination (ACE) (Mathuranath *et al.* 2000) takes about 20 minutes to administer. It consists of six components evaluating separate cognitive domains. A maximum score of 100 is weighted as follows: orientation (10), attention (8), memory (35), verbal fluency (14), language (28), and visuospatial ability (5). The orientation and attention components are as in the MMSE. The memory section involves the recall of three items from the MMSE, a name and address learning and delayed recall test, plus semantic memory. The language component includes naming 12 line drawings, comprehension, repeating words and sentences, reading regular and irregular words, and writing. Visuospatial testing consists of copying overlapping pentagons (from the MMSE) plus a wire cube, and drawing a clock face. Verbal fluency consists of ‘P’ words and animals and requires separate scoring. The ACE has good sensitivity and specificity and appears to be able to distin-

guish between ‘functional’ and ‘organic’ disorders reasonably well (Fig. 3.1) (Dudas *et al.* 2005). A cut-off of 88 has been proposed for screening purposes.

Even after this fairly comprehensive screening, individual areas of cognitive function must be systematically explored, with the aim of covering each of the sections described below. Those which require most careful assessment in the particular patient will by now be apparent since attention will have been directed towards them by the history, the neurological examination and the cognitive deficits already displayed.

Box 3.2 Initial assessment of cognitive function

- 1** Take careful note of the patient’s *level of cooperation*: his willingness to apply himself to the test procedures will be fundamental to the amount of reliable information that can be obtained
- 2** Make a preliminary assessment of the *level of conscious awareness*: this must have an early priority since performance on all other tests may be affected by minor degrees of clouding of consciousness
- 3** Next assess *language functions*: much of what follows will depend on the accuracy of verbal communication. In addition to noting verbal ability, ask the patient to name a series of objects and to perform a series of simple commands
- 4** *Memory functions*, if not already tested, should be briefly examined as already described
- 5** *Visuospatial ability* should always be screened because non-verbal deficits of this nature may otherwise remain concealed. Ask the patient to copy simple designs (such as those in Visuospatial and constructional difficulties, later in chapter).
- 6** Test the integrity of *volitional movements* and at the same time of *right–left orientation* by asking the patient to point to various parts of the body. For example, ‘Touch your left ear with your left hand’, ‘Touch your left knee with your right hand’.

Fig. 3.1 Scatterplot of total scores in various diagnostic groups using Addenbrooke’s Cognitive Examination (ACE). Reference line is a score of 88, the recommended cut-off score on the ACE for screening purposes. (From Dudas *et al.* 2005 with permission.)

Level of conscious awareness

Impairment of consciousness is obvious when there is frank drowsiness or somnolence during examination. It is the detection of minor degrees of impairment that causes difficulties. There are no pathognomonic signs or tests for minor impairment of consciousness, and its detection is largely a matter for subjective clinical judgement based on a variety of clues.

Record any obvious impairment in the form of drowsiness or diminished awareness of the environment. Note fluctuations during examination, and question relatives or nursing staff about changes which occur from time to time during the day. Impairment may only become obvious towards nightfall or when the patient is fatigued.

Minor impairment will be suspected when the patient is dull, inert and uncertain in behaviour even though he is not drowsy, or when responses to external events are diminished. There may be a vagueness and hesitancy about the manner of speaking. Once the examiner suspects a reduction in the level of consciousness it can be helpful to repeat questions concerning dates and names of places, with the object of seeing whether consistent answers are given. Tests of orientation, attention, concentration and memory may be poorly performed, often with variability from one occasion to another. Judgement of the passage of time will often be markedly inaccurate. Attention will usually be ill sustained and ill focused, and the patient may tend to lose the thread in conversation. Lucid intervals may emerge from time to time and form a marked contrast to the general tenor of behaviour. Even when seemingly alert it may be discovered that the patient has failed to register on-going experiences, including those of the interview itself.

Simple procedures may be employed to assess capacity for sustained attention or 'vigilance' over a period of time. The patient may be asked, for example, to raise his hand whenever an 'A' is spoken, and a series of letters are then delivered in an even tone and at a constant rate. A more difficult version consists of raising the hand whenever any vowel is spoken, or whenever two vowels succeed one another. A written form of the test can easily be made by asking the patient to cancel all letters of a designated type on a printed sheet or in a passage of prose material.

If somnolent, can the patient be roused to full or only partial awareness? If his attention cannot be sustained, does he drift back towards sleep or does his attention wander onto other topics? When consciousness is severely impaired describe the nature of the stimulus required to evoke a response (e.g. conversation, firm commands, commands following arousal by shaking, painful stimuli) and the character of the response produced (e.g. a correct verbal reply or motor act, an incorrect and muddled response, failure to respond to commands but accurate localisation of a painful stimulus, ill-coordinated and ineffectual motor movements). The Glasgow Coma Scale (see Chapter 4, under Measuring head injury severity) will prove of value for monitoring progress in patients with seriously impaired consciousness.

Evidence for delirium, stupor or coma should be specified in detail.

Language functions

Language functions are conveniently examined under the six headings described below. Thorough examination of dysphasic disturbances can take considerable time, but in

the non-dysphasic subject screening need last only a few minutes. At the onset it is important to note whether the patient is *predominantly right- or left-handed*.

Motor aspects of speech

Note the quality of spontaneous speech and that in reply to questions. Minor expressive speech defects may only emerge when the patient is pressed to engage in conversation, to describe his work, his house, or some event in his life.

Is there any disturbance of articulation (dysarthria)? When slight dysarthria is suspected test ability to pronounce a phrase such as 'West Register Street'.

Is there slowness or hesitancy with speech production and is the output sparse? Conversely, is the output excessive with a definite pressure of speech (logorrhoea)?

Does he use wrong words, words which are nearly but not exactly correct, or words that do not exist? *Paraphasic errors* may be defined as 'substitutions within language' (Benson & Geschwind 1971) and exist in several forms; they may involve the substitution of one correct word for another, the distortion of one syllable within a word, or the production of a group of sounds with no specific meaning (neologisms).

Note whether words are omitted and sentences abbreviated (telegram style). Are there inaccuracies of grammatical construction (paragrammatisms)? Is the normal rhythm and inflexion of speech disturbed (dysprosody)? Is speech totally disorganised and incomprehensible (jargon aphasia)?

Observe carefully for perseverative errors of speech (see Chapter 2, Broca's aphasia, and Verbal fluency, later in chapter), also for reiteration of phrases just spoken (echolalia), of single words (pallilalia) or of a terminal syllable (logoclonia).

When defects are found, test whether automatic speech or the naming of serials is better preserved than conversational speech: ask him to repeat a well-known nursery rhyme or prayer, to count to 20, or to give the days of the week. Are emotional utterances or ejaculations preserved when formal speech is defective?

From the phenomenological point of view, Benson and Geschwind (1971) recommend a basic division into *fluent and non-fluent* forms of dysphasic speech, the former characterising posterior lesions and the latter anterior lesions. Fluent aphasias generally show clear articulation, the words are produced without effort, output is normal or excessive, paraphasic errors are frequent, phrase length is not curtailed, and normal rhythm and inflexion are preserved. Non-fluent aphasias show poor articulation, the speech is produced with obvious difficulty, output is sparse but nonetheless the content is meaningful when this can be discerned, phrase length is reduced to one or two words, and the rhythm and inflexion are disturbed.

Comprehension of speech

The understanding of speech must be separately assessed, whether or not production is defective. Even when the patient is mute or his utterances totally incomprehensible it is still necessary to determine whether he can understand what is said to him.

Can he point correctly on command to objects around him? Can he carry out simple orders on request, for example pick up an object, show his tongue? Failure can be misleading since it may be due to dyspraxia; thus if commands are not carried out, test whether he can signal his response to simple yes-no questions.

Can he respond to more complex instructions, for example walk over to the door and come back again, or take his spectacles from his

pocket and put them on the table. Can he follow a series of commands sequentially, for example go to the window, tap it twice, turn around, then come back again.

Marie's Three Paper Test is widely employed for the rapid assessment of mild comprehension defects. Three pieces of paper of different sizes are put before the patient. He is told to take the largest and hand it to the examiner, take the smallest and throw it to the ground, and take the middle-sized piece and put it in his pocket.

The understanding of prepositional and syntactic aspects of speech can be a sensitive indicator of minor comprehension difficulties. It is readily tested by providing the patient with three objects such as a book, pen and coin, then issuing increasingly complex instructions as follows: 'Put the coin on the book; put the coin and the pen under the book; tap the book and then the coin with the pen; put the book between the pen and the coin; place the book over the coin then put the pen inside it', and so on.

If comprehension of spoken speech is defective, test whether understanding of written words and instructions is better preserved. Test whether other hearing functions are intact, for example the startle response to sudden noise. Test for auditory agnosia by noting whether the patient can recognise non-verbal noises (clapping hands, snapping fingers, jingling money) or copy the production of such sounds when they are made outside the field of vision.

Repetition of speech

Can the patient repeat digits, words, short phrases or sentences exactly as you give them? The classic phrase for testing repetition is 'No ifs, ands or buts'. Successful repetition involves both motor and sensory parts of the speech apparatus and also the connections between the two. Failure in repetition may occur despite adequate spontaneous articulation and good comprehension. Paraphasic errors often emerge most clearly in the testing of repetition.

Word finding

Does the patient have difficulty in finding words during conversation, or use circumlocutions? Test specifically for nominal aphasia by asking him to name both common and uncommon objects (for example the parts of a wrist watch, and other objects in the room). Include an examination of his ability to name colours.

Nominal aphasia may be the only language disturbance in patients with cerebral damage and must therefore always be tested with care. Ease of word finding is inversely related to the frequency of occurrence of the word in the language, and the detection of slight nominal aphasia requires testing with objects whose names occur relatively infrequently such as 'buckle', 'pointer' or 'dial', but not 'watch' or 'strap'; 'lapel' or 'knuckle', but not 'button' or 'finger'; 'radiator' or 'linoleum', but not 'picture' or 'carpet'.

Reading

Present the patient with the written names of objects in the room and ask him to point to them. If this is performed correctly, present him with written instructions to perform specific actions.

Test his ability to read aloud, and determine whether he understands what he has read. If the patient fails to read aloud it is still necessary to assess whether he has read, since some aphasics comprehend well even though they fail to read aloud.

Writing

Test ability to write spontaneously and to dictation. Examine written productions for substitutions, perseverations, spelling errors and letter reversals. Is copying better preserved than writing to dictation? Is spelling out loud better preserved than spelling on paper? Is the writing of habitual material (signature, address) relatively intact? Are numbers written more accurately than words or letters?

The main syndromes of language impairment can be distinguished by the pattern of breakdown in the above examination. Table 3.2 summarises performance on the different tests of language function in relation to the syndromes of aphasia described in the chapter on neuropsychology.

Verbal fluency

Verbal fluency must be separately assessed, even when there is no other form of language disturbance, since fluency is characteristically impaired with frontal lesions.

A simple technique is to ask the patient to give as many words as he can think of beginning with a certain letter of the alphabet, for example 1 minute for words beginning with F, then 1 minute for A and 1 minute for S (letter or phonological fluency). The total achieved on this 'FAS' test should be in excess of 30. Norms are available in relation to the patient's age and educational level (see Lezak 1995). Alternatively, the patient may be asked to give the names of animals or the names of objects found in a kitchen (semantic fluency).

The number of words accomplished will often be strikingly low even though there is no evidence of dysphasia. This accords with the impoverishment of spontaneous speech that may be observed with frontal lesions. It can be necessary to allow the patient a full minute over his attempts at each category, since words may be rapidly produced initially then tail off in noteworthy fashion. Frequent perseverations and out of category items are a distinctly 'frontal' feature. The effect is more pronounced with left frontal lesions than right. Most individuals will produce more animals than F, A or S words, although patients with loss of semantic knowledge (e.g. Alzheimer's disease or frontotemporal dementia) may show a reverse pattern. Corresponding deficits can also be demonstrated on a design fluency test, but in this case the task is more affected by right frontal lesions than left (Jones-Gotman & Milner 1977).

Number functions

Test the patient's ability to perform simple arithmetical operations – addition, subtraction, multiplication, division – in relation to his educational and occupational background. Assess his ability to handle money correctly.

Can he count objects and make a rough estimate of the number of matches laid before him? Can he give the average size and weight of a man? Can he estimate the size of various objects in the room?

Test his ability to read and write numbers of two and more digits.

Table 3.2 Performance on tests of language function in different varieties of dysphasia. (After Benson & Geschwind 1971.)

	Spontaneous speech	Comprehension	Repetition	Naming	Reading	Writing
Pure word-deafness	F	–	–	+	+	+(not to dictation)
Pure word-blindness (alexia without agraphia)	F	+	+	+	–	+
Pure word-dumbness	NF	+	–	±	+	+
Pure agraphia (agraphia without alexia)	F	+	+	+	+	–
Primary sensory (Wernicke's) dysphasia	F	–	–	±	–	–
Primary motor (Broca's) dysphasia	NF	±	–	±	Aloud – Compr ±	–
Nominal dysphasia	F	+	+	–	±	±
Conduction dysphasia	F	+	–	±	Aloud – Compr +	–
Isolation syndrome	NF	–	+	–	–	–
Transcortical motor dysphasia	NF	+	±	–	Aloud – Compr +	–
Transcortical sensory dysphasia	F	–	+	–	–	–
Alexia with agraphia (visual asymbolia)	F	+	+	+	–	–

Compr, comprehension; F, fluent speech productions; NF, non-fluent speech productions.

Memory

Full examination of memory will always be required along the lines already set out in Chapter 2 (Disorders of memory). Special attention should be directed at recent memory and new learning ability.

A convenient and sensitive method for supplementing the assessment of new learning ability consists of testing the patient's capacity for learning supra-span lists of digits (Drachman & Arbit 1966; Warrington 1970). The normal digit span is first determined (as in Memory, earlier in chapter), then ability to extend the list by one or two items is assessed by repeated presentations. Amnesic subjects can perform adequately on the straightforward digit span test, but show a dramatic breakdown in performance as soon as this is exceeded.

Simple paired-associate learning may also be tested, as outlined in Memory.

Non-verbal memory should be tested in addition to verbal memory by asking the patient to reproduce simple geometrical figures (such as those shown in the next section) after an interval of 5 minutes.

Visuospatial and constructional difficulties

Patients with visuospatial agnosia may make no complaints, thus failing to direct attention towards the problem. It is important therefore to include tests which betray such difficulties when a cerebral lesion is suspected.

Test the patient's ability to judge the relation between objects in space: to estimate distances, to say which of two objects is nearer to him, and which is larger. Can he with eyes closed indicate the spatial order of objects in the room around him?

Visuospatial agnosia is often associated with constructional dyspraxia and the distinction between the two defects is usually far from clear-cut (see Chapter 2, Visual object agnosia). Constructional dyspraxia is tested as follows.

Test ability to connect two dots by a straight line, and to find the middle of a straight line and of a circle. Test ability to draw simple figures such as a square, circle and triangle. Ask the patient to copy a series of line drawings of increasing complexity such as those shown below.

The test may be made more difficult by removing the model and asking the patient to draw the figure from immediate memory. Ask him to draw a house, a bicycle, a clock face and set the hands, and to indicate the principal towns on a rough map of England. Note particularly whether he shows neglect of one half of visual space or crowds material into one part of the paper. Test ability to construct simple figures when presented with sticks or matches. Can he construct a triangle and a square, or copy more complex designs? Can the patient assemble a simple jig-saw puzzle, or reassemble a piece of paper that has been cut into several fragments?

The copying of a range of geometrical figures has the virtue of being graded in difficulty and of providing a permanent

record. Most normal subjects will succeed in copying at least the first four of the test figures illustrated earlier in this section. Free drawing of a house or bicycle has the advantage of being more natural and also more difficult. It often reveals more subtle forms of defect, but can be hard to interpret since normal individuals vary considerably in drawing skill. Sometimes highly characteristic defects may emerge, as when windows are placed in the roof or outside the main body of the building. The drawing of a clock is particularly useful in showing how accurately the figures can be spaced around the dial, or in revealing unilateral neglect of space by the omission of figures from one half of the dial. The use of sticks and other materials for constructional tasks gives

the opportunity to observe the patient's capacity to improve his performance and to alter mistakes. Similarly a standardised version of clock drawing (CLOX; see Fig. 3.2) enhances the reliability of the test and enables the comparison of performance to instruction versus copying. Only the former relates to specific cognitive impairment and executive function deficits.

Other agnosic disturbances

Other forms of agnosia are very rare. Before concluding that agnosia is present it is essential to try to exclude impairments of primary perception as the cause of failure on a test (such as impaired visual acuity, field defects or deafness). Firm

Fig. 3.2 Qualitative differences in CLOX performance in (a) a normal elderly control, (b) a patient with Alzheimer's disease and (c) a patient with non-cortical vascular disease. (a) An 82-year-old elderly control: EXIT25 score 8/50 (score greater than 5/50 indicates impairment); MMSE score 29/30. (b) A 74-year-old married white woman with Alzheimer's disease: EXIT25 score 21/50 (score of 24/50 is comparable with 6-year-old child or residents requiring skilled nursing); MMSE score 12/30. (c) A 74-year-old right-handed white man with a history of coronary artery disease (status post myocardial infarction), hypertension, non-insulin-dependent diabetes mellitus, and falls: EXIT22 score 24/50; MMSE score 28/30. (From Royall *et al.* 1998 with permission.)

indications of an agnosic problem will often be obtained by finding that an object which cannot be identified through one sensory modality is immediately identified through another.

Can the patient describe what he sees and identify objects and persons? Ask him to name a particular object in a group exposed to view and to describe its use, or if aphasic to indicate its use (*visual object agnosia*). If he fails, test whether he can identify the object by other senses such as touch. Ask him to name the colours of objects, to indicate their colour on a chart and to group objects according to their colour (*colour agnosia*). Ask him to describe a meaningful situation in a picture shown to him (*simultanagnosia*). Is his recognition of faces defective (*prosopagnosia*)? Ask him to point out a named person known to him among a group or to name photographs of relatives or of well-known public figures.

Auditory agnosia will already have been assessed (see under comprehension of speech, Chapter 2).

Tactile agnosia is tested by asking the patient to identify objects by touch with the eyes closed. Each hand must be tested separately. Care must be taken that other sensory information (such as the rattle of money) does not give the necessary clue for identification. Ask him to name the objects and to describe their shape, texture and use. In the event of failure, test whether the objects can then be identified by vision. If dysphasic, his responses must be assessed by testing selection from a group of objects exposed to view.

Dyspraxia and related disturbances

Before diagnosing dyspraxia it is essential to make sure that the patient's difficulties cannot be explained on the basis of muscular weakness, incoordination or profound sensory disturbance. Many dyspraxic patients are also dysphasic, so care must be taken to check whether instructions are understood. To prove the existence of dyspraxia it is necessary to show that a movement not made under one set of conditions (e.g. on command) can be performed under others (e.g. spontaneously), or that movements of equal or greater complexity can be made under other circumstances. It is also necessary to exclude simple unwillingness to cooperate. Because of the complexities of this area of dysfunction it is advisable in all cases to make a careful note of what the patient does, how he does it and what he fails to do (Critchley 1953). The examination should test the integrity of learned movements both to command and to imitation. It must also encompass the capacity for making familiar gestures, and for using objects in pantomime and in reality.

Test the patient's ability to carry out purposeful movements to command, such as holding out the arms, crossing legs, showing teeth, screwing up eyes or nodding the head. Test each hand separately for making a fist, opposition of thumb and little finger, pronation and supination (*ideomotor dyspraxia*).

Test ability to rise from a chair on command and to turn around (*whole body dyspraxia*).

Test ability to imitate postures of the hand and arm demonstrated by the examiner, and to adopt with one limb the posture imposed on the other.

Test expressive and make-believe movements such as knocking at a door or waving goodbye. Ask the patient to demonstrate how he would brush his teeth, use a hammer or kick a ball.

Test the patient's ability to carry out complex coordinated sequences of movements, such as taking a match from a box and striking it, winding a watch, cutting with scissors, or folding a piece of paper and putting it in an envelope (*ideational dyspraxia*).

Does the patient show undue difficulty with dressing and undressing, get muddled when inserting limbs into clothing, or try to put garments on the wrong way round (*dressing dyspraxia*)?

Tests of frontal lobe function

When frontal damage is suspected certain tests are specially indicated. Many of these tap 'executive functions' in that they examine the initiation, planning and regulation of goal-directed behaviours. Others assess capacities for abstract thinking, categorisation or judgement. Only some are suitable for bedside examination, which will therefore often need to be supplemented by neuropsychological tests as described in Chapter 2 [under Executive (frontal lobe) syndromes]. These have been helpfully combined and validated in the form of the Frontal Assessment Battery (FAB) (Box 3.3) (Dubois *et al.* 2000). It includes simple items on conceptual similarity; verbal fluency; Luria's motor tests; tests of alternating movements and response inhibition; and utilisation behaviour. Table 3.3 shows the comparative scores on the MMSE, a dementia rating scale and the FAB in groups of patients with a variety of neuropsychiatric conditions associated with executive function deficits, including Parkinson's disease, progressive supranuclear palsy, frontotemporal dementia, and corticobasal degeneration. The FAB is better able to distinguish the groups from controls than the MMSE. Another useful instrument designed to be incorporated into a clinical assessment is the Executive Interview (EXIT25) (Royall *et al.* 1992). According to the authors, it defines the behavioural sequelae of executive dyscontrol and provides a standardised clinical encounter in which they can be observed.

Other bedside tests include the *Cognitive Estimates Test* (see Cognitive Estimates Test, later in chapter), which assesses the patient's capacity for making realistic practical judgements of size and number.

Ask, for example, 'What is the largest object normally found in a house? What is the best paid job in Britain today? How fast do race-horses gallop? What is the length of the average man's spine?'

The idea is that a cognitively intact person would be able to answer these questions through reflection and common sense. Pathological responses are those that are way outside the limits of a reasonable guess. So in the question about a man's spine, a correct answer would obviously be somewhat less than the average height of a man but more than a couple of feet.

Behavioral observations can be equally important in pointing to frontal dysfunction. Note whether the patient is

Box 3.3 Content, instructions and scoring of the Frontal Assessment Battery (FAB)**1 Similarities (conceptualisation)**

'In what way are they alike?'

A banana and an orange

A table and a chair

A tulip, a rose and a daisy

Score

Only category responses (fruits, furniture, flowers) are considered correct.

Three correct: 3

Two correct: 2

One correct: 1

None correct: 0

2 Lexical fluency (mental flexibility)

'Say as many words as you can beginning with the letter S, any words except surnames or proper nouns.'

The time allowed is 60 seconds.

Score

Word repetitions or variations (shoe, shoemaker), surnames or proper nouns are not counted as correct responses.

More than nine words: 3

Six to nine words: 2

Three to five words: 1

Less than three words: 0

3 Motor series (programming)

'Look carefully at what I'm doing.'

The examiner, seated in front of the patient, performs alone three times with his left hand the series of Luria (1966): fist–edge–palm. 'Now, with your right hand do the same series, first with me, then alone.' The examiner performs the series three times with the patient, then says to him 'Now, do it on your own.'

Score

Patient performs six correct consecutive series alone: 3

Patient performs at least three correct consecutive series alone: 2

Patient fails alone, but performs three correct consecutive series with the examiner: 1

Patient cannot perform three correct consecutive series even with the examiner: 0

4 Conflicting instructions (sensitivity to interference)

'Tap twice when I tap once.'

To be sure that the patient has understood the instruction, a series of three trials is run: 1-1-1.

'Tap once when I tap twice.'

To be sure that the patient has understood the instruction, a series of three trials is run: 2-2-2.

The examiner then performs the following series: 1-1-2-1-2-2-2-1-1-2.

Score

No error: 3

One or two errors: 2

More than two errors: 1

Patient taps like the examiner at least four consecutive times: 0

5 Go–no go (inhibitory control)

'Tap once when I tap once.'

To be sure that the patient has understood the instruction, a series of three trials is run: 1-1-1.

'Do not tap when I tap twice.' To be sure that the patient has understood the instruction, a series of three trials is run: 2-2-2.

The examiner then performs the following series: 1-1-2-1-2-2-2-1-1-2.

(continued)

Score

No error: 3

One or two errors: 2

More than two errors: 1

Patient taps like the examiner at least four consecutive times: 0

6 Prehension behavior ('utilisation') (Lhermitte 1983; Lhermitte *et al.* 1986)

'Do not take my hands.'

The examiner is seated in front of the patient. Place the patient's hands palm up on his knees. Without saying anything or looking at the patient, the examiner brings his or her hands close to the patient's hands and touches the palms of both the patient's hands, to see if he will spontaneously take them. If the patient takes the hands, the examiner will try again after asking him 'Now, do not take my hands.'

Score

Patient does not take the examiner's hands: 3

Patient hesitates and asks what he has to do: 2

Patient takes the hands without hesitation: 1

Patient takes the examiner's hand even after he has been told not to do so: 0

apathetic, disinhibited, unkempt or lacking in normal social graces.

Topographical sense and right-left orientation

Does the patient have difficulty in finding his way about the ward (topographical disorientation)? Does he confuse his bed with other people's? Can he describe the relations between parts of the ward or of his own house? Can he describe the route from home to hospital? If necessary test his ability to follow a simple route in the ward or hospital.

Can the patient point on command to objects around him on the right and on the left? Ask him to move on command right and left parts of the body, and to point to individual parts on the right and left side of his own body, and of the examiner sitting opposite him. Can he perform complex instructions like 'touch your right ear with your left hand' or 'pick up the left hand coin with your left hand and place it in my right hand'?

Body image disturbances

Body image disturbances will often be revealed by the patient's behaviour or his own subjective complaints, but

sometimes special tests or questions will be required to elicit them. Asking the patient to make a rough drawing of a man will sometimes give the first indication of body image disorder (Cohn 1960).

Test for *finger agnosia*. Ask the patient to move on command or point to individual fingers, his own and the examiner's. Kinsbourne and Warrington (1962) describe various tests which have proved to be more sensitive indicators of finger agnosia than the conventional tests. In one such, two of the patient's fingers are touched simultaneously and he is asked to state how many fingers lie between them.

Test for disturbance of identification of other body parts (*autotopagnosia*). Ask the patient to move on command and to name various parts of his body, to point to them and to parts of the examiner's body.

Note any evidence of *unilateral unawareness or neglect* of the body. When present this will usually involve the left side. Does the patient utilise the left hand normally in bimanual activities? Is the left side of the body relatively neglected in washing, combing or dressing? When attention is drawn to such defects does he recognise them and correct them?

Table 3.3 Comparative scores on the Mini-Mental State Examination (MMSE), Dementia Rating Scale (DRS) (Mattis 1988) and Frontal Assessment Battery (FAB): study group characteristics. (From Dubois *et al.* 2000 with permission.)

Population	N	Age (years)	MMSE	Mattis DRS	FAB
Controls	42	58.0 ± 14.4 ^a	28.9 ± 0.8 ^a	141.0 ± 2.4 ^a	17.3 ± 0.8 ^a
Patients	121	64.4 ± 9.3 ^a	25.5 ± 4.8 ^a	118.0 ± 19.1 ^a	10.3 ± 4.7 ^a
PD	24	59.4 ± 12.9 ^{c,g}	28.0 ± 1.9 ^{i,j}	134.0 ± 15.2 ^{c,g,i}	15.9 ± 3.8 ^{c,g,i}
MSA	6	65.0 ± 10.5	25.7 ± 3.9 ⁱ	127.0 ± 16.2 ^e	13.5 ± 4.0 ^{e,f}
CBD	21	67.4 ± 8.1 ^{b,c}	26.4 ± 3.8 ^b	123.7 ± 15.0 ^{b,e}	11.0 ± 3.7 ^{b,e,d}
PSP	47	66.9 ± 7.0 ^{g,h}	26.2 ± 3.7 ^h	117.7 ± 15.2 ^{g,h}	8.5 ± 3.4 ^{d,f,g}
FTD	23	60.3 ± 8.5 ^{b,h}	20.7 ± 6.3 ^{b,h,i}	101.5 ± 20.0 ^{b,e,h,i}	7.7 ± 4.2 ^{b,e,i}

Values are presented as mean ± SD. Significantly different at $P < 0.05$ for ^acontrols and patients; ^bfrontotemporal dementia (FTD) and corticobasal degeneration (CBD); ^cParkinson's disease (PD) and CBD; ^dprogressive supranuclear palsy (PSP) and CBD; ^eFTD and multiple system atrophy (MSA); ^fPSP and MSA; ^gPD and PSP; ^hFTD and PSP; ⁱPD and FTD; ^jPD and MSA.

Determine whether he has unusual subjective sensations or beliefs about the limbs of one half of the body. Do they feel as though absent or changed, either intermittently or continuously (*hemisomatognosia*)?

Does the patient ignore or show lack of concern about an injured or functionally defective part of the body, for example a left hemiparesis or hemianopic field defect (*anosognosia*)? He may verbally deny the defect or deny ownership of the affected body part.

Other general indications of organic cerebral disorder

Note the ability of the patient to *sustain attention* during the above test procedures. Did he *fatigue unduly easily*? Was he able to *shift attention* readily from one task to another? Did he show *perseveration* in the use of words or in response to commands (Chapter 2) Note and describe any evidence of *lability of mood* or *euphoria*. Were emotional responses *exaggerated, flattened or lacking*? When confronted with a task beyond his ability did he show evidence of a *catastrophic reaction* (see Mood, under Mental state, earlier in this chapter)? Did he show *impulsiveness, disinhibition or over-familiarity* at any point during the testing? Did the patient *appreciate his failings* and show *appropriate concern*? Did he use *evasions or excuses* to cover up his deficits?

Examination of the mute or apparently inaccessible patient

States of mutism, stupor and apparent inaccessibility may be due to organic brain disease or to psychiatric disorders such as depression, catatonic schizophrenia or conversion hysteria. In all cases it is necessary to carry out a detailed neurological examination and to assess the apparent level of conscious awareness (as outlined above) before considering other aspects of the problem.

The differential diagnosis of stupor is considered in Chapter 1. In addition to the intracerebral causes it is essential to bear in mind the possibilities of physical illness, especially metabolic, and to examine for physical complications of stupor such as hypotension or retention of urine. It is also important to remember that in stupors due to non-organic psychiatric illness the patient's comprehension of remarks made in his presence may be intact despite appearances to the contrary.

Stupor, semicoma and hypersomnia

The definitions of these terms are not sufficiently precise to be used as the sole description of the phenomena they comprise. The following features should therefore be described separately.

To what extent does the patient dress, feed himself or cooperate with feeding, and attend to matters of hygiene and elimination?

Are the eyes open or shut? If open, are they apparently watchful and do they follow moving objects? If shut, do they open in response to stimulation, and is there resistance to passive opening?

Assess the patient's response to graded stimulation as outlined in Chapter 1. When aroused does he become briefly alert and verbally responsive?

Is the physical posture comfortable, constrained, awkward, bizarre, or in any way indicative of possible delusional beliefs? Does the patient resume a previous posture if moved or when placed in an awkward position? Do movements display special meaning, for example on a possible delusional basis or in response to hallucinatory experiences?

Is the facial expression constant or varying, alert or vacant, blank or meaningful? Is it secretive, withdrawn, indicative of sadness, hopelessness or ecstasy? Does it betray attention to hallucinatory experiences?

Is there any physical or emotional reaction to what is said or done to the patient or within his hearing? Does he show an emotional response when sensitive subjects are discussed? Does he show signs of irritation or annoyance when moved against his wishes?

Examine the state of the musculature. Is it relaxed or rigid? Is rigidity increased by passive movements? Examine for negativism, *flexibilitas cerea*, automatic obedience and echopraxia. Note evidence of resistiveness, irritability or defensive movements during examination.

In the neurological examination pay special attention to evidence of raised intracranial pressure or of diencephalic or upper brainstem disturbance: thus examine for papilloedema, observe equality and reactivity of pupils, note quality of respiration, look for evidence of long tract deficit in the limbs, and test for conjugate reflex eye movements on passive head rotation.

After recovery, examine for memory of events occurring during the abnormal phase and for fantasies or other subjective experiences occurring at the time.

Mutism

Mutism is a condition in which the person does not speak and makes no attempt at spoken communication despite preservation of an adequate level of consciousness. It may sometimes be the only abnormality in otherwise normal behaviour.

Is it elective, confined to some situations, or in relation to some persons but not others? Is the patient disturbed by it as shown by gesticulations or evidence of distress? Does he attempt to communicate by signs? When offered paper and pen does he communicate in writing?

Distinguish mutism from severe motor aphasia, anarthria, aphonia, poverty of speech or severe psychomotor retardation. Is partial vocalisation preserved, are emotional ejaculations possible, and can simple yes-no answers be given? Test separately for ability to articulate (to whisper or make the lip movements of speech) and ability to phonate (to produce coarse vocalisations or to hum). Can he cough? Does he speak very occasionally and briefly on restricted themes? Does he reply or signal responses to some questions but only after a long delay? In the distinction from aphasia it is important to remember that the most profoundly aphasic patient is never mute; he is always able to make some speech sounds, even if these are restricted to crude syllabic stereotypes or repeated expletives (Benson 1973).

A careful history from informants may sometimes enable distinctions to be made more readily than from examination alone.

Psychometric assessment

The clinical value of psychological testing in the field of organic psychiatry has been much debated. Overenthusiastic

claims have sometimes followed the introduction of new tests and procedures for the identification of cerebral dysfunction, and have had to be tempered later in the light of experience. However, even when the claims themselves have been modest the psychiatrist has often misunderstood the situation, and has expected a degree of exactitude from psychometric testing that is unrealistic. Collaboration with clinical psychologists, especially those with special expertise in neuropsychology, is extremely helpful, both in diagnosis and in management, provided a jointly balanced view is taken of the situation. In the diagnosis of brain damage the psychiatrist's and the psychologist's approach are both in their own ways fallible, but each may usefully supplement the other.

The limitations of psychometric tests must be appreciated. There appears to be no single test that will differentiate brain-damaged patients from others without some degree of overlap, and even the most skilful selection of groups of tests will occasionally produce misleading results. Accordingly, test results should only be interpreted in conjunction with all other sources of information relevant to the issue in question. The worst service to psychometry, and to the patient, is likely to come from attempts to rely on test scores viewed in isolation. Similar disappointment would be expected to follow if any clinical diagnostic procedure were singled out and given unique importance. It is essential therefore to retain a general clinical impression as a back-up to the detailed findings.

Advantages

As diagnostic instruments, psychological tests have certain definite advantages over the ordinary procedures of clinical assessment. The tests can be given in strictly standardised form and the results are usually scored numerically. Hence they can be validated on large groups of patients, so that norms can be established and the extent of individual variation gauged with some precision. In these respects they represent a marked advance on the psychiatrist's assessment of the mental state. With their aid one can talk meaningfully in terms of *probabilities* where the presence or absence of brain damage is concerned, and the level of probability is often crucial in deciding what action to pursue. Similarly, the measures can be repeated on more than one occasion, permitting accurate comparisons over an interval of time. This can be invaluable when equivocal findings have emerged at the first consultation; after establishing a baseline the patient's progress can be charted with some accuracy, and any evidence of decline will be highlighted.

Psychological testing can also concentrate in detail on an individual area of functioning which has come under suspicion. Minor degrees of memory impairment or verbal disability, for example, can be pursued with much more thoroughness by psychometric tests than in the clinical interview. The structure of such deficits can also be explored in greater detail. It is here that the psychologist must sometimes be prepared to sacrifice the rigid standardisation of his

approach in order to follow the leads that emerge. Piercy (1959) has argued cogently that some kinds of evidence are better assessed by an experienced human observer than by a standardised procedure; the nature of the failure can be important and this is not always obvious from the score alone. In other words, the advantages of the standardised approach must not be allowed to become an unduly restrictive influence or valuable information will sometimes be lost.

Limitations

Sensitivity and specificity

Typically a test is standardised on groups of subjects known to be suffering from brain damage, and groups in whom this is known to be absent by independent criteria. Nevertheless, few tests are given to large representative populations of 'normal' individuals in which a certain level of 'abnormal' test results is to be expected. In clinical use the test will often be applied to borderline problems in which other evidence of brain damage is equivocal, and here it will not yet have established its credentials. The difficulty in establishing the sensitivity of the test in equivocal cases lies in the problem of obtaining a final arbiter of brain damage. Follow-up of disputed cases can help by displaying the *predictive value* of the test, but such studies have not been carried out extensively.

Attention and motivation

All tests require a certain level of attention and cooperation. Consequently they are vulnerable to emotional disturbance and other influences that have nothing to do with brain damage. Tests which distinguish well between brain-damaged and healthy subjects may therefore give misleading results when applied to certain psychiatric patients. Depression, for example, may disrupt performance on sensitive tests of memory, and schizophrenic thought disorder may lead to poor performance on tests of abstract thinking. Thus any test which is to be usefully employed for differential diagnosis between organic and non-organic psychiatric illness must first be standardised on patients suffering from a wide range of mental disorders.

Theoretical basis

Common misconceptions have also concerned the nature of brain damage itself, and the constancy of its relationship to the behavioural deficits that follow. Tests have sometimes relied heavily on unitary theories of cerebral dysfunction, and many of those put forward as global indicators of 'brain damage' pay little regard to what is known of regional cerebral organisation. Thus tests which sample a restricted aspect of cognitive activity may fail to identify cerebral lesions that are sufficiently circumscribed to leave that particular function intact. Purely verbal tests, for example, may fail to detect visuospatial difficulties resulting from a restricted lesion of the non-dominant hemisphere.

'Untestable' patients

Many patients may simply be too disturbed to undergo systematic psychometric testing, although obtaining meaningful test results from a disturbed patient will reflect the skill and ingenuity of the tester. Here the experienced clinician comes into his or her own: engaging the distractible patient for a few minutes to determine their level of orientation; using objects around them to test praxis, naming, and recognition. Can the patient recall something in the newspaper by his side? Can she report on what she has been watching on the TV? Does he recognise the person next to him and know his name? Given a pen, can she write her name or draw a picture? Patients are never untestable, although the clinician may be incapable of testing them.

Evidential status

Psychometric testing is sometimes regarded, erroneously, as objective. True, unlike bedside assessments, such testing is quantifiable. It should be transparent – the results must be interpreted but such interpretation is rational and governed by rules – valid and reliable. Good inter-rater reliability implies that the tester's characteristics should not influence the test results; standardising testing methods and high standards of clinical training ensure this. However, despite all this, psychometry is rarely objective since testing requires the cooperation of the subject. This may be important in medicolegal and some clinical contexts where a patient may wish to influence the results in one direction or another.

Applications

From the foregoing it will be clear that the questions asked of the psychologist must be realistic, and should reflect some knowledge both of the limitations and special advantages of the psychometric procedures available. It will usually be helpful to discuss the patient fully beforehand in order to focus on the problems to be solved. Requests that the psychologist should 'exclude the possibility of brain damage' or 'localise the lesion' will not yield unequivocal answers, but to ask for collaboration in assessing the *likelihood* of brain damage, focal or diffuse, may add valuable evidence to that already available. The job of lesion localisation is generally delegated to the neuroradiologist. Establishing a baseline level of ability prior to treatment or with a view to tracking decline is extremely valuable. Apart from diagnosis, psychometry can also be valuable where rehabilitation is concerned. Areas of relatively intact function can be identified, and problems highlighted on which re-education should be concentrated. Progress can be monitored with a fair degree of accuracy, enabling ultimate goals to be discerned.

In the sections that follow some of the available tests are briefly described. Some provide essentially qualitative information, although the great majority yield numerical scores. Some rely on profiles of comparison between different functional capacities, or help to demonstrate the fall from esti-

mated levels of premorbid intelligence (e.g. the National Adult Reading Test). Others concentrate on certain areas alone, such as perception, language or memory, although obviously considerable overlap will often occur. Mention is also made of certain aptitude tests, often initially designed for healthy individuals, but also useful as a guide to the rehabilitation and resettlement of brain-damaged patients. Questionnaires and rating scales which have been employed with severely brain-damaged subjects are also discussed.

The tests themselves vary widely in the extent to which they have been validated and the adequacy with which norms have been established. This is not the place to attempt a thorough review of their respective credentials, but rather to give an outline for the clinician of commonly used tests, their aims and procedures. Details can be found in the compilations produced by Crawford *et al.* (1992a) and Lezak (1995).

Standardised tests of intelligence and memory

Wechsler Adult Intelligence Scale

The Wechsler Adult Intelligence Scale (WAIS), produced by the Psychological Corporation of America, is an extensively standardised instrument for the measurement of intelligence, providing separate scores for 'verbal' and 'performance' abilities. Possible deterioration from estimated or established premorbid levels can be assessed, and this alone can yield important information about the likelihood of brain damage. Qualitative interpretation of different subtest scores may indicate areas of special cognitive difficulty. The current version is WAIS-III (Wechsler 1997).

Verbal subtests (untimed except for arithmetic)

- 1 Information: 29 questions covering a wide variety of information and arranged in order of difficulty.
- 2 Comprehension: 16 items in which the subject must explain what should be done in certain circumstances, the meaning of proverbs, etc. This aims at measuring practical judgement and common sense.
- 3 Arithmetic: 14 mental arithmetic problems set in the context of everyday activities.
- 4 Similarities: 14 items in which the subject must say in what way two things are alike.
- 5 Digit Span: lists of 3–9 digits to be reproduced forwards and 2–8 digits to be reproduced backwards.
- 6 Vocabulary: 35 words graded in difficulty for which the subject must give the meaning.
- 7 Letter–Number Sequencing: the object is to extract separate sequences of letters and numbers from a mixed sequence containing both (optional).

Performance subtests (all timed except matrix reasoning)

- 1 Digit Symbol: the subject must follow a simple code in matching symbols to digits, as quickly as he can.
- 2 Picture Completion: the subject is shown 20 pictures of human features, familiar objects or scenes, and must say what important part is missing from each.

- 3 Block Design: this is similar to the Kohs' Block Design Test. The subject must reproduce designs with red and white blocks.
- 4 Picture Arrangement: 10 sets of cartoon pictures must be arranged in sequence so as to tell a sensible story.
- 5 Matrix Reasoning (replaces object assembly from WAIS-R): the subject chooses the next in a sequence of abstract coloured symbols.
- 6 Symbol Search: the subject has to look for either of two symbols in a sequence.

The raw score on each subtest is transmuted into a standard score (scaled score), which represents the individual's distance from the mean in terms of the distribution for that particular subtest. By this procedure all subtest scores are expressed in units that can be compared one with another. WAIS-III subtests may be grouped to form indices: verbal comprehension, perceptual organisation, working memory and processing speed. Abbreviated forms of the test are commonly used in clinical practice and the Psychological Corporation have an official version, the Wechsler Abbreviated Scale of Intelligence (WASI) comprising vocabulary, block design, similarities and matrix reasoning. The scores on the WAIS is standardised to give a mean IQ of 100 with one standard deviation equal to 15 IQ points; the 50% confidence limits range from 90 to 110 and the 95% confidence limits from 70 to 130. Below 70 is regarded as in the mental retardation range.

The current WAIS-III was intended to be of greater utility to neuropsychologists than its predecessors (see Tulskey & Haaland 2001). For example, measurement of letter-number span appears to be a good index of working memory and matrix reasoning (derived from Raven's Progressive Matrices, a non-verbal measure of IQ in adults and children; Raven *et al.* 1992), of 'fluid' intelligence, and is less contaminated by performance speed which tends to be affected non-specifically in many clinical groups. In general the battery has significant advantages over many 'proper' a priori neuropsychological tests: extensive population age-corrected norms, strictly operationalised procedures, and reasonable face validity in terms of underlying cognitive processes. The WAIS-III is designed to be allied to the Wechsler Memory Scale (WMS-III) so memory impairment can be judged to be consistent with or disproportionate to general abilities (see below). It may also be administered by any non-specialist clinical psychologist. On the other hand, it is clearly sensitive to education, language and other ethnic and cultural factors (like many tests). It takes time to complete and while relating the WAIS-III to previous versions and the childhood version (WISC) is fairly straightforward, it is not without problems.

As a neuropsychological test, brain damage may be reflected in discrepancies between the verbal and performance IQs. In very general terms, verbal subtests will tend to be impaired by lesions in the dominant hemisphere, and those involving visuospatial functions by lesions in the non-dominant hemisphere, although verbal-performance discrepancies cannot be used as a reliable guide to laterality of

brain damage. The likelihood of a verbal-performance discrepancy being pathological can be gleaned from the scoring manual. *Deterioration indices* involve comparisons between other contrasting groups of subtests. 'Hold' tests are identified which are found to be relatively impervious to the effects of brain damage, whereas 'Don't hold' tests show early decline. The former include subtests that reflect the use of old knowledge (e.g. vocabulary and information), whereas the latter require speed or the perception of new relations in verbal or spatial content (digit symbol and block design). One of the most useful applications of an IQ score derived from the WAIS is comparison with an earlier score (an index of premorbid IQ or at the very least a broad estimate of premorbid functioning from previous occupation or educational attainment) in providing *prima facie* evidence of decline as in a dementing condition or following a brain insult.

The application of the WAIS as a diagnostic instrument has been criticised on theoretical grounds, in that the reliability of subtests taken individually is not sufficiently high to allow a confident interpretation of any but the largest differences between them. Scatter can result not only from pathological processes but also from differences in educational, occupational and cultural factors. Nevertheless, qualitative interpretation of subtest scores may provide useful clinical information, yielding important pointers for verification by more detailed testing. In my opinion, the WAIS is undervalued as an assessment tool in neuropsychiatry.

National Adult Reading Test

A simple technique for yielding an approximate estimate of general intelligence consists in administering a series of words to be read aloud (Nelson 1982; Nelson & Willison 1991). Nelson and McKenna (1975) introduced this rapid method using words from the Schonell Graded Word Reading Test, and Nelson and O'Connell (1978) then modified it by drawing up a list of words spelled in an irregular manner (e.g. ache, bouquet, naive, sidereal). The level of word reading ability achieved by an adult has been shown to correlate highly with intelligence and, being well practised and overlearned, it proves to be relatively resistant to influences which impair other aspects of cognitive function.

It is this last aspect which makes the test especially useful. The authors showed that even in patients with dementia the ability to read words declined little if at all, at least in the patients used in the samples they examined. Thus subjects without evidence of brain disorder gave results closely comparable to patients with cerebral atrophy, even though in the latter the WAIS IQ had deteriorated considerably. It was possible to show that estimates of premorbid intelligence derived from the National Adult Reading Test (NART) were more stable even than those derived from the vocabulary subtest of the WAIS. The validity of the test in this regard has since been confirmed in further studies (Crawford *et al.* 1990)

and use of the NART has spread to other clinical groups such as patients with schizophrenia and bipolar affective disorder. However, the test has come under criticism, with evidence that in patients with dementia of moderate severity it may yield an underestimate of premorbid competence (O'Carroll *et al.* 1995). Also, the NART is prone to floor effects.

After administering the NART, regression equations may be used to obtain an estimate of minimum premorbid intelligence, and discrepancies between this and current WAIS IQ. It may also be used to estimate premorbid levels of verbal fluency (Crawford *et al.* 1992b). The test has obvious limitations, however, especially for non-native speakers of English, subjects who were always poor readers, or who have acquired reading difficulties or dysarthria. Versions of the NART in other languages are available, although abundant irregular words are a special feature of English and simply do not arise in, for example, everyday Italian.

Memory tests

Wechsler Memory Scale (WMS-III)

Wechsler's battery of memory tests aims at measuring several different aspects of memory by rapid standardised procedures. As with the WAIS, it too was updated in 1997 and quite radically so. Two of the three visual subtests that had been in WMS-R (figural memory and visual paired associates) were deleted and the third (visual reproduction) was retained as optional. The WMS-III introduced the new Family Pictures and Faces subtests that use genuine stimuli such as photographs rather than just abstract shapes. The old 'attention/concentration' factor was reconceptualised as 'working memory'. This is assumed to be parallel to the WAIS-III working memory factor but there are different subtests: the spatial span, assumed to be a visual analogue of the digit span task (Tulsky 2004).

Clinicians routinely examine differences between an individual's performance on immediate and delayed memory tasks as a way of differentially diagnosing encoding versus retention deficits. In the WMS-III, evaluation of the Immediate Memory Index (IMI) and the General Memory Index (GMI) allows such a comparison. The logical memory story (A) is largely unchanged, and there is a new second story (B) which is now repeated a second time to assess the benefit of repetition. The test is also followed by a 30-item yes-no recognition memory subtest.

All the subtests except spatial span are given in immediate (1) and delayed (2) conditions. Altogether they form indices: Immediate Memory (composed of Logical Memory 1, Verbal Paired Associates 1, Faces 1, and Family Pictures 1); General Memory (composed of Logical Memory 2, Verbal Paired Associates 2, Faces 2, and Family Pictures 2); and Working Memory (composed of Letter-Number Sequencing and Spatial Span).

- Information and Orientation (optional).

- Logical Memory examines the immediate recall of two short stories, the second of which is presented twice. The subject is asked to retell the stories immediately or after a delay of around 30 minutes. After the delayed condition the subject is asked yes-no questions about the stories.
- Faces: 24 photographs are presented followed by 48 photos and the subject is asked to say which out of these he recognises.
- Family Pictures: photos of a family and a series of scenes. The subject has to remember information, such as who was doing what and where. Both Faces and Family Pictures have immediate and delayed presentations.
- Word Lists (optional): 12 semantically related words are presented orally to be recalled. There are four learning trials. Then a new 12-word list is presented as before. Then the subject has to recall as many words as he can from the first list. After delay, recall of the first list is again tested. Finally, 24 words are read and the subject indicates, one by one, if it was on the first list.
- Verbal Paired Associates: eight pairs of words are read to the subject. Then the first of each pair is read and the subject has to remember its pair. There are four trials of the list in different orders. All pairs are novel (compare the previous version, which had hard and easy (commonly associated) word pairs). In the delayed condition, the first of each pair is again read out and the corresponding word is sought. All words are then read and subject has to indicate whether each is old or new.
- Visual Reproduction (optional) involves the immediate recall of five geometrical figures. The subject must draw what he remembers after seeing each card for 10 seconds. In the delayed condition there are recall, recognition, copying and matching tests.
- Letter-Number Sequencing: a string of alternating letters and numbers are presented orally. The test is to repeat the numbers in ascending order followed by the letters in alphabetical order.
- Spatial Span: a series of patterns is shown on a three-dimensional board. The examiner points to them one by one. The subject then has to repeat this. Subsequently the subject points to the blocks in reverse order.
- Mental Control (optional), e.g. reciting days of the week.
- Digit Span (optional): forwards and backwards.

Neuropsychological tests

Detailed knowledge of the huge range of neuropsychological tests currently available is not required for the practising neuropsychiatrist. However, an idea of the nature and administration of a few commonly used tests is very useful in interpreting reports, recommending tests and discussing their results in an informed way with colleagues. Interested readers should consult Lezak (1995) and Anastasi & Urbina (1997). Table 3.4 lists the main classes of tests with examples not described above. Details of some of the more commonly used tests are given in the Appendix.

Special and ancillary investigations

Further investigations will often be required when an organic basis is suspected for psychiatric disorder. Certain routine tests should ideally be performed on all psychiatric inpatients, including estimation of haemoglobin,

Vineland Social Maturity Scale

erythrocyte sedimentation rate, urea, electrolytes and blood glucose, liver function tests, thyroid function, calcium and phosphate, serological tests for syphilis, chest radiograph and routine urine examination. The patient's temperature should always be taken, with 4-hourly recording if minor rises are suspected. These serve as screening tests for coincidental as well as causally related physical disorders. Other investigations will be indicated on the basis of the history and clinical examination when specific disorders are suspected. An important principle is that investigations should always be planned to give the maximum required information with the minimum of inconvenience to the patient. Investigations without discomfort or risk will obviously be more readily undertaken than those which carry the possibility of pain or complications. For example, skull radiography, electroencephalography (EEG) and computed tomography (CT) will sometimes be performed even when the level or suspicion of organic involvement is low, whereas lumbar puncture and other invasive procedures will be reserved until very specific and important questions need to be answered. The yield of abnormal CT results in psychiatric patients from various series has been described by Roberts and Lishman (1984).

Few of these tests have well-defined sensitivities and specificities for neuropsychiatric disorders and a great deal of judgement and consideration is required when embarking on elaborate investigations. Special investigations will only yield useful data if they have been discussed properly with the professional carrying them out. The indications for these and other investigations are detailed in the relevant chapters later in the book. The special investigations required in connection with some of the rarer causes of dementia are outlined in Chapter 9, and see Love 2005. Certain other investigations of particular relevance to cerebral dysfunction are discussed in detail below.

Electroencephalography

The EEG has the important advantage over many other procedures that it is safe and without discomfort to the patient. It is accordingly used extensively when organic psychiatric disorders are suspected. Furthermore, it remains the major non-invasive means of determining the physiological or functional state of the brain, as opposed to its anatomical status. However, certain marked limitations in its diagnostic usefulness must be borne in mind.

Characteristics

EEG rhythms are conventionally classified into four components according to their frequencies: delta (<4 Hz), theta (4–7 Hz), alpha (8–13 Hz) and beta (>13 Hz) (Storm van Leeuwen *et al.* 1966). The normal EEG has a well-developed alpha rhythm, maximal in the occipital and parietal regions, which attenuates on opening the eyes and reappears when they are closed again. It similarly attenuates when the patient engages in mental activity such as simple mental arithmetic. The

average voltage of the alpha rhythm is 30–50 μV with spindle-shaped modulations. Small amounts of other rhythms are allowable provided the alpha activity is well developed. Beta activity is seen mainly in the precentral regions, and low-voltage theta becomes more obvious with relaxation and drowsiness. Delta activity is normally seen only in very young children and during sleep.

Lambda waves are saw-toothed in form and characteristically situated over the occiput. They reflect small eyeball movements. Mu rhythm has a characteristic waveform and a frequency within the alpha range; it is commonly present in the rolandic area and is diminished by contralateral limb movement (Toone 1984). K complexes are brief bursts of high-voltage slow waves that may emerge during non-REM (rapid eye movement) sleep.

Abnormal EEG elements that can be important in diagnosis include the following.

- *Spikes* are high peaked discharges that rise and fall abruptly and stand out above the general amplitude of the other waves.
- *Sharp waves* rise steeply then fall more slowly, and may occupy the alpha, theta or delta range.
- Composite elements may consist of spikes alternating with delta waves (*spike-and-wave* or *wave-and-spike* discharges) or slow waves preceded by several spikes (*poly-spike and wave*). Wave-and-spike discharges occurring at a rhythm of 3 Hz constitute the classic EEG feature of simple absence attacks; those faster and slower than this may be referred to as *wave-and-spike variants*.

Abnormal rhythms and other elements can be generalised, unilateral or focal, and may be described as synchronous or asynchronous depending on the coincidence of their appearance in different leads.

Various activating procedures may be used to clarify marginal abnormalities, or to reveal those concealed in the resting record. Hyperventilation is used to increase the excitability of cortical cells, probably mainly as a result of hypocapnic constriction of cerebral vessels leading to cerebral hypoxia (Meyer & Gotoh 1960). Epileptic foci and other disturbances may emerge more clearly. Photic stimulation consists of repetitive light flashes of varying frequency. Within certain ranges of flash frequency (especially 8–15 Hz) the occipital alpha rhythm adjusts itself to the flash rate (occipital 'driving'), and paroxysmal abnormalities may emerge in the form of high-voltage complex elements spreading to the frontal and temporal regions. Seizure patterns may emerge, and a generalised seizure may even be provoked. Sleep may be induced by barbiturates if it does not occur naturally. This can be useful in activating the spike or sharp wave discharges of epilepsy, especially those arising within the temporal lobes. Thiopental may be given intravenously and typically induces beta activity, often in the form of discrete runs or spindles. The induced beta activity is commonly less well developed at the electrodes over the site of damage in the affected temporal lobe. Other drugs may occasionally be employed for the activation of seizure patterns but only

under skilled supervision in specialised centres. Anticonvulsant medication may be withdrawn prior to EEG and telemetry studies in people suspected of having non-epileptic attack disorders (see Chapter 6).

In addition to the normal electrode placements over the scalp, sphenoidal, nasopharyngeal or foramen ovale electrodes can be valuable for locating discharges from the antero-inferior portions of the temporal lobes. These are chiefly used when assessing the suitability of epileptic patients for temporal lobectomy. Much may also be gained from depth electrode studies, or by recording directly from the exposed cortex at operation (electrocorticography). These procedures can obviously be undertaken only in special centres.

Limitations

In many ways, EEG has failed to satisfy early expectations as a diagnostic aid for reasons discussed by Kiloh *et al.* (1981), although more quantitative methods of analysis can improve its yield as a test (see Hughes and John 1999 for review). Accordingly it must only be interpreted with its limitations clearly in mind. Moreover, much of its traditional advantage in being non-invasive has now been eroded by the introduction of modern brain imaging techniques (Toone 1984).

In the first place, the EEG can be normal in patients with obvious cerebral dysfunction, especially if only a single recording is relied on. It is probably true to say that a normal EEG never excludes any clinical condition, but can merely serve to diminish the probability of its existence. Conversely, a certain proportion of healthy individuals will exhibit abnormal EEGs. The EEG is particularly sensitive to such physiological variables as level of awareness, acid-base equilibrium and blood sugar level. Such physiological changes in the record are indistinguishable from those associated with many pathological states, and can readily be misinterpreted as evidence of disease.

Again, with rare exceptions, the patterns obtained have little diagnostic specificity, and the EEG should only be used as an additional source of information to add to the evidence of the history and clinical examination. It can be a valuable aid in localisation but is of little help in pathological diagnosis. Even with regard to localisation it is known that a focal lesion can occasionally be associated with disturbance some distance away, or alternatively give rise to generalised EEG abnormalities. For these reasons the most useful help will be obtained from the investigation when the person interpreting the record is fully acquainted with all relevant clinical information about the patient's illness.

There can be added difficulties in psychiatric patients, in that mental disorders of apparently non-organic origin are known to be associated with an increased incidence of abnormalities in the EEG. This can sometimes cloud the issue when it comes to the differential diagnosis between organic and non-organic psychiatric conditions. Whereas perhaps

10–15% of normal subjects show some abnormality on EEG, this figure has sometimes been found to be higher among patients with neurotic disorders. The abnormalities in such patients commonly lie just outside the normal range, with an excess of generalised theta or beta rhythms of rather low amplitude. Patients with bipolar affective disorder have been reported to show marginally abnormal records in up to 20% of cases, although again the finding is far from consistent. Schizophrenia is sometimes associated with more definite abnormalities, in perhaps one-quarter of cases. Catatonic schizophrenia shows abnormal records more commonly than other varieties. However, these changes are not constant, failing to appear in some patients and sometimes varying from one attack to another in the same patient.

In patients with disorders of behaviour and personality the incidence of abnormalities is perhaps highest of all. Classic studies by Hill and Watterson (1942) found that 48% of patients diagnosed as psychopathic had abnormal EEGs compared with 15% of controls, and among aggressive psychopaths the proportion rose to 65%. The majority of the abnormalities in patients with personality disorder appear to reflect cerebral immaturity, and are of a type that would be accepted as normal in a very much younger age group. Sometimes the so-called immaturity may be the result of past cerebral insults, even of birth injury, but the great majority appear merely to be associated with delayed maturation. Thus the abnormalities tend to decrease with age, and this may be accompanied by a parallel improvement in behaviour.

Another difficulty with psychiatric patients can be the result of treatments currently or recently given. Many of the widely prescribed drugs affect the EEG, in some individuals to a marked extent. Fenton (1974) and Kiloh *et al.* (1981) have reviewed the main changes that occur. Barbiturates and other sedatives increase fast activity and sometimes produce a small amount of diffuse theta or even delta activity. Most sedatives also tend to aggravate epileptic discharges. On the other hand, anticonvulsants other than barbiturates have little effect on the EEG. Chlorpromazine in low dosage may disturb alpha activity, with the occasional appearance of slow frequencies. In dosages much higher than tend to be used nowadays, it may produce generalised delta waves or hypersynchronous high-voltage discharges. Chlorpromazine also potentiates epileptic discharges. Clozapine has dose-related epileptogenic properties. Similar changes are produced by most other antipsychotics, tricyclic antidepressants and lithium. Benzodiazepines (e.g. diazepam) are usually associated with increased fast activity.

Electroconvulsive therapy can render the EEG hard to interpret for a time. Each fit is followed by generalised theta and delta activity, which becomes more persistent as successive treatments are given. After three or four treatments spaced at intervals of 2–3 days the abnormal rhythms may persist in the intervals between, often with frontal prepon-

derance. As the course of treatment proceeds the disturbance becomes more widespread and of higher voltage, and alpha activity may disappear. Individual patients differ in the severity of these effects and in the time taken for return to normality (around 1–3 months).

Uses

This brief description of some of the difficulties surrounding the interpretation of the EEG is necessary before discussing situations where it can serve a useful purpose (Smith 2005). In general terms, suspicions of abnormality of brain structure or function are confirmed by the EEG in more than 60% of cases with around 10% false positives, based on a large group of patients aged over 50 years investigated for organic disease (Leuchter *et al.* 1993). Hence it can bring added information in psychiatric patients when the question of an organic basis for the illness has arisen. In diagnostically obscure cases one can look for clues which may indicate the need for further investigation. A single focus of abnormally fast or slow activity will always suggest the presence of a cerebral lesion and must be followed up further, likewise gross asymmetries of normal or abnormal activity between the hemispheres. EEG also plays a part in the differentiation between organic and non-organic psychiatric illness, though caution must be observed. A normal record will be of little help in the distinction, but it will certainly be less easy to maintain a diagnosis of a purely psychogenic disturbance in the presence of a grossly abnormal record.

Epilepsy

The disturbances seen in epileptic subjects are considered in detail in Chapter 6. Characteristic epileptic discharges consist of spikes, sharp waves or wave-and-spike complexes. When recurrent these are very strong evidence in favour of an epileptic process. In primary generalised epilepsy, wave-and-spike complexes may consist of runs of classic 3-Hz spike and wave, but in the presence of grand mal attacks they are commonly somewhat faster or consist of variants with poly-spike and wave. Other abnormalities common in epileptics, but without the same degree of specificity, include paroxysms of symmetrical delta activity, bursts of theta, or a diffuse excess of delta and theta. Epilepsy that originates within the cortex shows a spike and sharp wave focus, or local spike discharges either singly or in groups. These often betray the point of origin of the seizures, although sometimes they are transmitted widely to other areas. Temporal lobe epilepsy often shows spike discharges over the temporal region, but occasionally the record can be normal until sleep is induced and sphenoidal or nasopharyngeal electrodes are employed.

The principal value of the EEG in epilepsy is to distinguish patients with a discharging cortical focus from those with primary generalised epilepsy. In patients without an aura to their grand mal attacks there may be no other means of

making the distinction. The EEG can localise the cortical lesion, indicate its extent, and whether it is unilateral or bilateral, although this has become less important with the advent of magnetic resonance imaging (MRI).

On the broader question of the diagnosis of epilepsy, the EEG can be useful but is not an infallible guide. Epileptiform discharges are found in occasional normal persons, in many degenerative brain disorders and in some patients with psychosis or personality disorder. Conversely, in some 20–30% of patients with epilepsy, a single routine EEG will be normal. In exceptional cases the record can remain normal even during an attack, as in some cases of Jacksonian and psychomotor epilepsy when the foci are so discrete, and of such low voltage, that they fail to reach the surface electrodes. The recognition of the epileptic nature of a group of symptoms must therefore remain primarily a clinical task, but one which obtains firm confirmation from the EEG in the majority of cases. Where the clinical features are dubious this confirmation can have a decisive influence on the diagnosis and future management. Classic spike-and-wave discharges, for example, may resolve doubts when an adequate witnessed account of attacks is not forthcoming. And in temporal lobe epilepsy, the EEG can sometimes point directly to the diagnosis in patients who have hitherto been considered to suffer from 'hysteria', anxiety attacks or short-lived psychotic reactions. The EEG is particularly valuable in confirming or excluding non-convulsive status epilepticus, which can present as a confusional state.

Space-occupying lesions

Space-occupying lesions are revealed by the EEG in a high proportion of cases but is no longer used for this purpose. A focal delta wave focus will constitute strong presumptive evidence of a cerebral tumour, especially when combined with the other features outlined in Chapter 5. Alternatively, it may give the first indication of a developing cerebral abscess when this arises as a complication of a generalised infection. A subdural haematoma in the elderly sometimes presents with a psychiatric picture, and the EEG can be the factor that alerts one to the diagnosis. Typically, there is diminished amplitude or suppression of cerebral rhythms over the affected hemisphere, and some irregular slow activity on the affected side, although the contralateral hemisphere may be affected as well. One must also beware of the occasional cases with well-defined but utterly misleading foci, even sometimes locating the tumour or haematoma to the wrong side of the head.

Cerebral infarction

With cerebral infarctions the EEG can be of help in gauging prognosis. Patients with minimal changes during the acute episode can generally be expected to make a good recovery, and also patients in whom the EEG changes resolve steadily

from an early date. However, an EEG that becomes normal while neurological deficits persist suggests that little further clinical improvement can be expected.

Head injury

After head injury the EEG may again sometimes help in gauging prognosis (see Chapter 4) or in pointing to an organic component in disturbances which have seemed to be purely psychological in origin. EEG changes may occasionally foreshadow the development of post-traumatic epilepsy, but the interseizure record remains normal in a high proportion of patients even when fits have already become established.

Encephalitis

In encephalitis the EEG, together with examination of the cerebrospinal fluid (CSF), can be a valuable means of following progress. Abnormalities consist of diffuse irregular slow waves and scattered sharp waves, with slowing or reduction in alpha activity. Seizure patterns (e.g. periodic epileptiform discharges) are not uncommon in the acute stage and if bilateral confer a poor prognosis on herpes simplex encephalitis (Fig. 3.3). There may be a warning of complications and of permanent brain damage when slow waves persist. The appearance of new spikes or spike-and-wave complexes raises the possibility that secondary epilepsy will develop. In subacute sclerosing panencephalitis the EEG changes described in Chapter 7 have high diagnostic value.

Metabolic disorders

In metabolic disorders the EEG is a sensitive indicator of cerebral insufficiency, and can reflect worsening or improvement of the clinical condition with a fair degree of accuracy. The changes lack specificity for the various metabolic disorders, being for example similar in hypoglycaemia, anoxia, hypokalaemia, carbon dioxide retention or vitamin B₁₂ deficiency. Nevertheless, they can provide important information in patients who present with indefinite features in the mental state. They may help to confirm the organic basis for paranoid syndromes or disturbances of behaviour in patients who are only minimally confused. Alternatively, when organic features are well developed the EEG may help in the sometimes difficult distinction between reversible causes and progressive brain pathology. Obrecht *et al.* (1979) have demonstrated the value of the EEG in patients with acute confusional states in general hospital practice, particularly in helping to distinguish metabolic and other systemic disorders from intracranial pathologies.

The earliest changes are slowing of the alpha rhythm along with diminution of voltage. Later there is progressive slowing and disorganisation, with runs of theta that come to replace all other activity. Finally, in metabolic coma regular high-voltage delta activity appears, sometimes bilaterally synchronous and sometimes more random in distribution. In deep coma, when the patient is quite unresponsive, the

Fig. 3.3 Herpes simplex encephalitis: left-sided slow activity and repetitive periodic epileptiform discharges. (From Smith 2005 with permission of BMJ Publishing Group Ltd.)

amplitude of the EEG diminishes and ultimately the record becomes flat and featureless.

Disturbance of consciousness

Disturbance of consciousness will produce EEG slowing even when very mild and when cognitive difficulty can be hard to detect on clinical examination. This can be shown by serial recordings, and can occasionally be useful in the retrospective diagnosis of minimal degrees of clouding of consciousness. The absolute frequency of the dominant rhythm is less important than the degree of slowing. Thus 8–9 Hz may be abnormal if it has replaced alpha of a higher frequency. This explains why patients with clouding of consciousness can have an apparently normal EEG. When slowing has reached 5–6 Hz the characteristic disruption of activity on eye opening no longer occurs, representing the physiological correlate of the reduced impact of perceptions derived from the environment. Fluctuations in the severity of delirium, as reflected in outward behaviour, prove not to be related to changes in the underlying metabolic disturbance as reflected in the EEG, but to be more closely tied to psychological and environmental factors.

While there is often a relationship between the degree of EEG slowing and level of impairment of consciousness, this is not invariable. Delirium tremens is an obvious exception, in that during profound delirium the EEG may be normal or show fast activity of low to moderate voltage rather than slowing of rhythms. Lipowski (1990) suggests that slowing of the EEG is characteristic of delirium that presents with

reduced alertness and wakefulness, whereas in hyperactive delirium fast activity may be superimposed on this, sometimes with features resembling those of REM sleep.

The EEG can be of some diagnostic help in comatose patients. Comas due to metabolic disturbance will show diffuse high-voltage delta activity as described above, whereas in barbiturate overdosage there will be augmented amplitude and an increase in fast frequencies. Space-occupying lesions may be indicated by focal abnormalities, or epileptic activity may be revealed. Pseudocoma due to conversion disorder, psychosis or affective disorder would be expected to give rise to a normal or near normal EEG. The record will show responsiveness to auditory and visual stimuli.

Presenile and senile dementias

In the dementias the degree of EEG abnormality appears to be more closely related to the rate of progression of the disorder than to the degree of intellectual impairment at a given point in time. Briefly, in dementia of the Alzheimer type the commonest abnormality is accentuation of the normal EEG changes with ageing, and may therefore be difficult to diagnose with confidence. Alpha activity is slowed in frequency and reduced in quantity, and diffuse theta or delta rhythms tend to appear. The vascular dementias show a similar picture, though often with focal features where local cerebral infarctions have occurred. Presenile Alzheimer's disease is associated with a particularly high incidence of abnormalities. Alpha activity tends to disappear, and is replaced

Fig. 3.4 Characteristic EEG findings in sporadic Creutzfeldt–Jakob disease: periodic complexes at approximately 1 per second, and very low amplitude featureless background between complexes. (From Smith 2005 with permission of BMJ Publishing Group Ltd.)

with irregular theta on which runs of delta activity may be superimposed. Pronounced flattening of the record will raise the possibility of Huntington's chorea, whereas repetitive spike discharges or characteristic triphasic sharp wave complexes may be indicative of Creutzfeldt–Jakob disease (CJD) (Fig. 3.4).

In all these conditions the EEG abnormalities may fail to develop in a significant proportion of mild to moderate cases, and even advanced dementia can occasionally exist alongside a normal EEG. Moreover, with some exceptions, the changes that occur lack specificity for the illnesses in question. Nevertheless, an EEG can be helpful in early and uncertain cases of dementia. In the previously mentioned study by Leuchter *et al.* (1993), 42% of patients with suspected dementia without clear impairment had an abnormal EEG, the figure rising to 65% in those with mild to moderate impairment. A normal EEG in such circumstances will make Alzheimer's disease unlikely, but will not exclude other varieties of dementia. The EEG may also help in the distinction between diffuse and focal lesions.

Finally, in elderly patients the EEG may aid differentiation between depressive pseudodementia and degenerative brain disease. A normal EEG in a patient who has been diagnosed as suffering from Alzheimer's disease or vascular dementia, and who shows features of depression, will at least suggest that the diagnosis should be reconsidered (Kiloh *et al.* 1981).

Event-related potentials (evoked potentials)

Incoming sensory stimuli are associated with brief changes in brain potentials, and these can be detected when suitable averaging methods are used to demarcate them from the background EEG activity. Successive epochs of EEG are summated and averaged by computer while repeated

visual, auditory or somatosensory stimuli are presented to the subject. The value of such techniques lies in their non-invasive nature and the minimal requirement for cooperation from the subject. Applied to almost any sensory modality, they can demonstrate abnormal sensory condition (Walsh *et al.* 2005). Moreover, certain late components of event-related potentials (ERPs), when coupled with minimal task demands, have proved to reflect psychological processes such as expectation and motivation, and to be abnormal in some psychiatric conditions.

The early components, generated within 20 ms or so from stimulus presentation, reflect neuronal activity in the sensory end organs and afferent pathways, and can be sensitive indicators of pathology in the auditory apparatus, optic pathways and brainstem. The value of visual pattern-evoked responses, brainstem auditory-evoked responses and somatosensory responses in the diagnosis of multiple sclerosis is described in Chapter 14) although yet again MRI is the main diagnostic tool. Wright *et al.* (1984) found that while pattern-evoked responses were normal in dementia, the major positive component (P2) to flash was considerably delayed, presumably because this is generated in association cortex rather than primary visual cortex.

However, the principal interest for psychiatry centres on the late components of ERPs elicited while the subject is engaged in some simple task (cognitive ERPs). Grey Walter *et al.* (1964) described *contingent negative variation* (CNV), observed when a subject was told to press a button in response to a flash of light which occurred 3 seconds after hearing a warning click. During the period of expectation a negative potential could be recorded from the scalp that increased steadily in amplitude until the button press was performed. Sutton *et al.* (1965) then showed that certain late potentials were a function of the uncertainty experienced by the subject

during simple test procedures, in particular the development of a large late positive potential some 300 ms after stimulus presentation (P300 response). In a typical test paradigm the subject listens to a series of auditory tones, most of which are identical in pitch, but with the random appearance of rarer stimuli at another pitch ('odd-ball' paradigm). The subject must attend carefully, and respond with a button press or make a mental count of the abnormal target stimuli. These then induce a series of late potentials: a negative deflection at approximately 100 ms (N1 or N100), a positive potential at 200 ms (P2), followed by N2 then P300 potentials at 300 ms. This last component has been extensively studied in relation to dementia and schizophrenia.

The P300 is significantly delayed in a majority of patients with dementia, and in proportion to the severity of the dementia (Gordon *et al.* 1986; Neshige *et al.* 1988). Moreover, there are indications that differences can be discerned in different varieties of dementia. Goodin and Aminoff (1986) showed that patients with subcortical dementia (Parkinson's and Huntington's disease) showed more severe delays in the P300 than in those with Alzheimer's disease, also longer delays in the earlier N1 and P2 components. The patients with Parkinson's and Huntington's disease differed from one another by greater P2 delay in the latter group. Observations have also been made in parkinsonian patients during 'on' and 'off' phases, with significant decreases in P300 latency while motor ability is improved (Starkstein *et al.* 1989). Goodin *et al.* (1990) found delayed latencies in all four components in patients with AIDS dementia, and to a lesser extent in many HIV-positive men who were clinically asymptomatic and with normal EEGs. It remains to be determined how far this may indicate subclinical brain infection and be of prognostic significance.

P300 findings in schizophrenia are more variable, but a majority of investigators have found diminished amplitudes of response, with or without abnormal latencies. Blackwood and Muir (1990) summarise studies showing differences between schizophrenic and depressed patients, and which may hold promise for circumscribing the boundaries of schizophrenia more closely. The P300 changes appear to be largely independent of the state of relapse or remission, and have been detected in asymptomatic relatives of schizophrenic patients; hence it is a good candidate for an endophenotype. Bramon *et al.* (2005) performed a meta-analysis on the results of several studies, yielding data on 472 relatives and 513 controls. The P300 amplitude was significantly reduced and latency significantly delayed in the relatives of schizophrenia patients. In a more general systematic review and meta-analysis, Bramon *et al.* (2004) considered 46 studies, including 1443 patients and 1251 controls. The pooled standardised effect sizes for (reduced) P300 amplitude was 0.85 (95% CI 0.65–1.05; $P < 0.001$) and for (increased) P300 latency –0.57 (95% CI –0.75 to –0.38; $P < 0.001$).

The other evoked potential to have attracted interest is the P50, an early response to usually auditory stimuli thought to

reflect attentional gating. The most useful variable is the ratio of the P50 response amplitude of the second or test stimulus to that of the first or conditioning stimulus. Normal subjects generally suppress the second response and typically have ratios of less than 40%. Subjects with schizophrenia and possibly their relatives show deficits in sensory gating, with P50 ratios generally greater than 50%. In the review by Bramon *et al.* (2004), 20 P50 studies were considered that included 421 patients and 401 controls. The effect size for the difference between cases and controls was just over 1.5 standard deviations (although latency did not differ).

Finally, a novel use of the P300 potential has been the attempt to distinguish between feigned and 'hysterical' sensory loss. By applying regular innocuous sensory stimuli and the occasional painful stimulus to the 'anaesthetic' area, Lorenz *et al.* (1998) found an attenuated P300 in the conversion patient but a normal response in a subject instructed to feign sensory loss.

Brain electrical activity mapping

Brain electrical activity mapping (BEAM) represents an attempt to gain maximal information from EEG and evoked potential data by displaying regional brain activity in the form of visual topographic maps. Several systems are now in use, the common aim being to extract visual information relevant to electrophysiological abnormality as a complement to structural and metabolic methods of brain imaging.

Duffy *et al.* (1979) introduced BEAM, using 24 scalp electrodes to record EEG and visual evoked responses. The EEG data were subjected to spectral analysis, and runs containing spike discharges were digitised. Extremely brief epochs of the evoked responses were displayed in quick succession. The spatiotemporal information obtained in this manner was displayed as colour-coded maps, interpolated values being calculated for points between electrode placements. Nowadays the input of many more electrodes is used and the system may be used to detect subtle changes during a cognitive task or at rest. Morihisa (1989) describes the strengths and limitations of such techniques and the findings that have emerged in relation to schizophrenia and developmental dyslexia, and uses have been described in relation to encephalopathies and attention deficit disorder. The value of BEAM in diagnosis has been largely superseded by the other brain imaging techniques.

Magnetoencephalography

Magnetoencephalography (MEG) has been developed during the past two decades as a method for studying brain electrical activity that is complementary to EEG. It aims to measure not the electrical activity directly but the minute magnetic fields which are a by-product of that activity. These are charted over extremely brief epochs of time, measured in milliseconds. The fundamentals of the

technique are described by Reeve *et al.* (1989), Fagaly (1990) and Andrews (1996).

The advantage of charting magnetic fields is that they are not attenuated and distorted by passage through the brain tissue, skull and scalp as are the electrical currents which constitute the EEG. Consequently localisation, whether superficial or deep, stands to be enhanced. And since the EEG is partly derived from radially orientated current sources and MEG from tangential sources, the simultaneous recording of both can provide complementary information with regard to the intracranial origin of electrical activity.

In recording the magnetoencephalogram a detection coil is placed in close proximity to the head surface and feeds information to a SQUID sensor (superconducting quantum interference device). Both the detection coil and the SQUID must be kept at superconducting temperatures, either by enclosing them in liquid helium in a vacuum-insulated chamber or by using closed-cycle refrigeration. This 'magnetometer' is capable of measuring extremely small variations in magnetic flux. The resulting information is fed through appropriate electronics to a data acquisition system. Since the SQUID must be protected from major changes in environmental magnetic fields it is usually necessary to carry out the recordings in a magnetically shielded room.

Although still largely a research technique, MEG has shown its potential for answering both fundamental and clinical problems. A principal virtue is its capacity to localise the source of electrical signals, with the equivalent of 100–300 recording channels, whether in the form of epileptic discharges or during studies of sensory evoked potentials (Barkley & Baumgartner 2003). Detection of deep foci has been used to enhance presurgical assessment in epilepsy, often in combination with EEG (Parra *et al.* 2004).

Considerable technical problems remain to be resolved before MEG becomes widely available as a clinical or research instrument. Apart from cost and logistics, there is the problem of developing valid models for localisation deep within the brain in the presence of multiple dipole sources with differing orientations. However, it is likely that the technique will contribute importantly to the understanding of the genesis of signals related to perception, cognition and behavioural responses, and might possibly clarify the site of major electrophysiological disturbances associated with psychiatric disorders. It could ultimately find a valuable place in the clinical investigation of patients with epilepsy (Reite 1990; Parra *et al.* 2004).

Lumbar puncture

Examination of the CSF can give valuable information in many clinical situations. It is usually a safe procedure but should never be undertaken lightly. The principal hazard is in patients with raised intracranial pressure and particularly when an intracranial tumour is present. The abrupt reduction of pressure due to withdrawal of fluid can bring about

tentorial herniation or a medullary pressure cone with fatal results. Even when the needle is quickly removed there may be continued leakage from the puncture hole in the dura mater so that complications can follow some time later. Lumbar puncture is therefore strictly contraindicated in the presence of papilloedema or when there are symptoms suggestive of raised intracranial pressure, except under skilled supervision and when neurosurgical help is immediately to hand.

In the absence of raised intracranial pressure the risk attached to lumbar puncture is small. Conversely, the risk of withholding it can be high. In psychiatric practice it will sometimes be indicated in patients who show disturbance of consciousness or unexplained change of behaviour, even in the absence of definite neurological signs. It can be a dangerous mistake to postpone the investigation on account of the severity of illness or uncooperative behaviour, although it will often be wise to delay in such circumstances until a CT scan and a neurological opinion have been obtained.

Walton (1993) reviews the information to be obtained from lumbar puncture. The pressure is raised in the presence of tumour, haematoma, abscess or cerebral oedema. A moderate rise may be seen in patients with severe arterial hypertension. The pressure may also be raised in certain rare disorders such as lead poisoning or hypoparathyroidism.

A pleocytosis implies inflammatory changes in the meninges, either primary as in meningitis, or secondary to cerebral infection as in encephalitis or cerebral abscess. Polymorphonuclear leucocytes predominate with pyogenic infections and may number many thousands per cubic millimetre, rendering the fluid turbid. Virus encephalitis shows mainly lymphocytes, though with some varieties there may be polymorphs in the early stages. The number of cells is normally rather low. When present, pleocytosis can be an essential observation for confirming the diagnosis. A moderate cellular reaction can similarly be important in the diagnosis of cerebral abscess, usually with 20–200 cells/mm³, most of which are polymorphs. In untreated general paresis, 5–50 lymphocytes/mm³ are usual, and as described in Chapter 7 the monitoring of the cellular content of the CSF is essential for judging the adequacy of treatment and for the early detection of relapse. A slight pleocytosis, nearly always of lymphocytes, may be present in other conditions including primary and secondary cerebral tumours, cerebral infarctions or multiple sclerosis.

Blood is found in the CSF after subarachnoid haemorrhage or when a primary intracerebral haemorrhage has extended to the subarachnoid space. Xanthochromia may persist as a yellow discoloration for several weeks thereafter. Xanthochromia in the absence of frank blood is also sometimes found with subdural haematomas.

An increased protein content is common to many conditions and can be difficult to interpret. The protein rises with meningitic infections and this can persist for some time after the pleocytosis has resolved. A moderate increase to 1.0 g/L

(100 mg/dL), or a little more, may occur with encephalitis, cerebral abscess, cerebral infarction, neurosyphilis, cerebral tumours and multiple sclerosis. Similar levels can be seen with cervical spondylosis or with myxoedema. In the latter situation it can be particularly misleading. With certain tumours such as meningiomas or acoustic neuromas the level is often considerably higher. Very high levels of up to 10 g/L (1000 mg/dL) without an accompanying cellular reaction is characteristic of the polyneuropathy of Guillain-Barré syndrome, also of spinal blockage from any cause.

The globulin fraction is raised in relation to the albumin in many inflammatory conditions. The gamma globulins are abnormally high, with a selective increase in the IgG fraction in the majority of cases of multiple sclerosis. Increases in the major immunoglobulins (IgG, IgA and IgM) are estimated using radioimmunoassay, immunoelectrophoresis and isoelectric focusing. *Oligoclonal banding* reflects the typical pattern of such changes in multiple sclerosis, but is also found in various forms of meningoencephalitis, subacute sclerosing panencephalitis and Guillain-Barré syndrome. Thus it is indicative of an immunological response rather than being diagnostic of a particular condition (Walton 1993). Immunoassay for protein 14-3-3 appears to be highly specific for CJD (see Chapter 9).

The sugar content of the fluid is greatly lowered or abolished in pyogenic meningitis. A moderate fall is found in tuberculous meningitis and can be a valuable pointer in differentiating this from the various forms of aseptic meningitis due to viral infection. The chloride content is also low in tuberculous meningitis.

Examination of films and culture of the fluid are important for determining the responsible organism when infection is present. Modern virological studies are highly sophisticated and sensitive (see Chapter 7) (Kennedy 2005). However, considerable time is required before the results of culture become available. The development of polymerase chain reaction techniques for the detection of viral DNA or RNA in the CSF yields an immediate and specific diagnosis with some infections, for example herpes simplex virus. Tests may be negative within the first 3 days and subsequently after acyclovir treatment (Tyler 2004). Examination of films may also reveal neoplastic cells, especially in carcinomatosis and the medulloblastomas of childhood. Serological tests for syphilis are important since it is possible that they may be negative in the serum in active cases of general paresis.

Thus in many situations examination of the CSF provides important information that contributes to the diagnosis. In some conditions such as encephalitis, general paresis and cerebral abscess it may be crucial in alerting one to the diagnosis. However, a normal CSF does not mean that a pathological process within the central nervous system (CNS) can be excluded. The degenerative processes responsible for the presenile and senile dementias do not as a rule show changes, and a completely normal fluid may be found in occasional

cases of encephalitis. Moreover, many pathological processes responsible for enduring brain damage and neuropsychiatric disturbance will have subsided by the time the patient is examined, and will have left a normal fluid in their wake.

Radiography of the skull

The chief indication for skull radiography is usually suspicion of a cerebral tumour, although cranial CT and MRI are invariably used as first-line investigations if available. There may be erosion or bony overgrowth over the vault due to a meningioma, or abnormal vascular markings indicative of a tumour or angioma. Special views may show erosion of the internal auditory meatus due to an acoustic neuroma. Osteolytic bone lesions may give the first indication of carcinomatosis or multiple myeloma. General thickening or 'woolliness' may indicate Paget's disease.

The next main focus of interest is the sella turcica. Decalcification or erosion of the posterior clinoid processes is an important indication of raised intracranial pressure, or the fossa may be enlarged due to a pituitary or suprasellar lesion.

Intracranial calcification provides other clues. The pineal is calcified in approximately 50% of adults and may display shifts of the midline structures. The choroid plexuses and the falx cerebri may occasionally be calcified as well. Calcification within the body of a tumour can be of direct localising value, similarly calcification within the walls of a large cerebral aneurysm. Other rare conditions include calcification within the basal ganglia in hypoparathyroidism (see Chapter 10), calcification within the nodules in tuberose sclerosis or in the cysts of cysticercosis.

Computed tomography

CT probably represents the most significant advance in the use of X-rays for diagnosis since their discovery and has established itself as invaluable in the diagnosis of cerebral disorder. The system is approximately 100 times more sensitive than conventional radiography systems, yet exposes the patient to no greater radiation dosage than a standard series of ordinary skull radiographs. There is no need for anaesthesia or any form of invasive procedure, rendering it entirely safe for patients who might be unfit for contrast neuroradiology.

The ventricular system is clearly shown along with certain of the basal cisterns. The cortical sulci are detectable, and readily so when enlarged. Within the cerebral substance variations in soft tissues of nearly similar absorption density may be displayed; thus the thalami and heads of the caudate nuclei are generally identifiable as discrete structures, also the internal capsule and optic radiations. The cortical grey matter mantle is visible over the surface of the cerebral hemispheres. Progressive refinements incorporated into more

recent machines have considerably increased the amount of detail displayed.

In investigating cerebral pathology the scan may show displacements of normal intracranial contents, but in addition many focal pathological processes produce changes in brain absorption density that enable lesions to be displayed directly. Space-occupying lesions are readily shown, including tumours, abscesses and haematomas. Local cerebral oedema is demonstrated, and infarction is revealed as a region of low absorption density.

The nature as well as the location of a tumour can often be demonstrated – whether benign or malignant, solid or cystic – as well as the degree to which surrounding oedema infiltrates brain tissue. A diffuse increase in absorption density is seen with meningiomas, colloid cysts and pituitary adenomas, whereas gliomas and metastases may be hyperdense or hypodense. A special advantage is the capacity to distinguish tumours from infarctions at an early stage, and in cases where angiography might well have been contraindicated. Intravenous injection of sodium iothalamate (Conray) can be used in doubtful cases to enhance the contrast between the tumour and surrounding brain tissue. In the management of strokes the differentiation between infarction and haemorrhage is relatively simple. This can be especially important if the patient is taking or due to take anticoagulants (Sandercock *et al.* 1985). The location, size and direction of propagation of intracerebral haematomas can be defined. After head injuries various important forms of cerebral pathology are displayed (see Chapter 4). In the acute stage of injury, scanning can be invaluable in demonstrating intracranial haematomas before the patient's deterioration makes them obvious to the surgeon.

The cerebral vasculature can now be imaged with impressive detail using helical CT. High-speed imaging is performed during the bolus administration of intravenous contrast. From a single pass of contrast medium, a three-dimensional reconstruction of the cerebral vasculature (including aneurysms and malformations) may be obtained that may then be inspected from any angle (Mazziotta 2000).

Cerebral atrophy shows as enlargement of the ventricles, broadening of the sylvian and interhemispheric fissures, and widening of the cerebral sulci, much as after air encephalography. Areas of relative translucency may be shown in the cerebral white matter in demyelinating disorders such as multiple sclerosis (Chapter 14) and Schilder's disease (Chapter 14). White matter changes may also be found in a proportion of demented patients and even sometimes in the healthy elderly (so-called leucoaraiosis), although MRI is the method of choice for revealing white matter pathology.

Significance of cerebral atrophy

Sometimes neuroimaging shows changes that are hard to interpret, particularly where cerebral atrophy is concerned. It is often easier to assess distortion by a space-occupying

lesion than to decide on the significance of minor ventricular enlargement. Occasionally, moreover, the ventricles may prove to be enlarged or the sulci prominent in patients who show no evidence of cerebral disorder. Such examples raise obvious diagnostic difficulties, and are a reminder that a range of normal variation must be allowed where the appearances of the brain are concerned.

It is now clear from CT that ventricular size increases with age even in healthy persons, and particularly so in the later decades of life. For example, Barron *et al.* (1976) examined 135 normal volunteers by CT, demonstrating a gradual increase from the first to the sixth decades followed by a dramatic increase from the age of 70 onwards. The range in ventricular size also became wider among the elderly subjects.

With regard to dementia there is usually an obvious association with evidence of atrophy, although this is not absolute in every case. Younger demented patients are more likely to show decisively abnormal findings, in comparison with their peers, whereas in the elderly there may be considerable overlap with healthy persons of equivalent age. Jacoby and Levy (1980) found on discriminant function analysis that CT measurements produced a correct prediction of dementia in 83% of elderly subjects, cortical atrophy being a rather better discriminator than ventricular size. Interestingly, however, patients over the age of 80 were significantly less likely to have large ventricles compared with those a decade or so younger, perhaps reflecting the more benign course of dementia in the very elderly. Hubbard and Anderson (1981) were able to show by detailed autopsy measurements that the ventricles were of normal size for age in approximately 40% of patients with senile dementia.

The severity of cognitive impairment in dementia has proved to be closely related to the degree of cerebral atrophy. Furthermore, Burns and Pearlson (1994) reviewed the many CT studies in this area, showing that significant correlations with cognition have emerged twice as often for ventricular as for cortical measurements and that cognitive deterioration on follow-up is paralleled by further ventricular enlargement. MRI is particularly valuable in the diagnosis of dementing illnesses and has more sensitivity than CT. There is a large body of work examining the diagnostic value of volumetric measures of particular anatomical structures, rather than the brain as a whole, such as the hippocampus, amygdala and entorhinal cortex. Such indices have good positive predictive value (around 70–80%) in the diagnosis of Alzheimer's disease even in comparison to mild cognitive impairment.

The advent of CT opened the flood-gates to volumetric studies in schizophrenia, starting with Johnstone *et al.* (1976) who confirmed the presence of cerebral atrophy (see Chapter 2) in historical post-mortem and air-encephalographic studies. Studies in affective disorder soon followed. CT and MRI studies are thus increasing our appreciation that a degree of cerebral disorder may play some part in

Fig. 3.5 Coronal magnetic resonance brain images illustrating different scanning sequences (see also Plate 3.1). T1, inversion recovery; T2, spin-echo; PD, proton density. (Courtesy of Dr Nancy Andreasen.)

contributing to a considerable range of mental illness. The degree of cerebral change encountered on CT will only rarely lead to difficulties with diagnosis, but on occasion it will be sufficient to call for detailed re-evaluation of the patient's illness. The cortical shrinkage and ventricular dilatation accompanying severe alcohol abuse will quite often be perplexing when the drinking history is unknown, likewise the appearances of atrophy that may accompany steroid administration (Bentson *et al.* 1978; Lagenstein *et al.* 1979). The latter appears to be largely reversible on discontinuation of the steroids. Minor reversible changes have also been reported in patients with anorexia nervosa (Palazidou *et al.* 1990).

Magnetic resonance imaging

The early 1980s saw the introduction of MRI and this has transformed diagnosis in neurology and neuropsychiatry (Besson 1990). It competes strongly with CT, yielding greatly superior anatomical and pathological information. Unlike CT it involves no X-irradiation but makes use of the magnetic properties of nuclei and their capacity to be excited by radio-frequency pulses.

Most routine MRI utilises the hydrogen nuclei of the tissues. In essence these are made to resonate in response to rapidly changing magnetic fields around them, and the signals they emit are then processed to yield a visual image based on their distribution and physicochemical state.

The patient is placed in a static magnetic field, varying in different machines from 0.5 to 4.0 T in strength. This produces a net alignment of the magnetic moments of the hydrogen nuclei in the tissues. Under such circumstances the nuclei 'precess' in a circular course about this axis, much as a spinning top will wobble. Brief bursts of radio-frequency pulses, applied at the appropriate frequency from a surrounding coil, augment the precession, and when the excitation pulse ends the nuclei return to their lower energy state. The electrical signals emitted from the tissues in the course of such energy changes can be

detected and analysed by computer to reveal the distribution of the hydrogen nuclei involved. Techniques are used to 'scan' the tissues systematically, yielding visual images much as with CT.

A variety of scanning sequences can be selected in order to optimise the particular parameters used in image reconstruction. *Repeated free induction decay* or *saturation recovery* (RFID or SR) produce images that reflect proton density. *Inversion recovery* (IR) sequences reflect the longitudinal or spin-lattice relaxation time (T1) of the protons as they return to their previous equilibrium in line with the axis of the static magnetic field. *Spin echo* (SE) sequences are differently derived to display the transverse or spin-spin relaxation time (T2), during which the spinning protons are relaxing in phase with one another but interacting with the spins of other nuclei. These different scanning sequences are each suited to different purposes in visual imaging. In T1 images the CSF appears dark in relation to brain tissue; in T2 images the CSF is light, with grey matter also light and the white matter dark (as illustrated in Fig. 3.5: see also Plate 3.1).

Special sequences

Fluid-attenuated inversion recovery (FLAIR) produces a heavily weighted T2 image. This in turn suppresses CSF signal and renders lesions at the parenchyma-CSF interface more conspicuous. This is particularly useful in demyelinating disorders where there may be plaques close to the ventricles. Another use is in highlighting hippocampal sclerosis in patients with temporal lobe epilepsy and hippocampal involvement in limbic encephalitis (Fauser *et al.* 2005) (Fig. 3.6). However, caution is needed in interpreting these images since the healthy hippocampus may also show mildly increased signal intensity.

Diffusion-weighted imaging (DWI) employs SE-based sequences that are sensitised to diffusion by strong magnetic field-gradient pulses. The biggest contribution of DWI has been in the detection of acute cerebral infarction, since water diffusion drops to half its normal value early on, giving a region of hyperintensity on DWI scans (Brammer & Fazekas 2002).

Diffusion tensor imaging (DTI) and *tractography*: diffusion in the brain is hindered by biological tissue, being relatively less impeded along the axis of myelinated fibres. This asymmetry is known as diffusion anisotropy. DTI exploits this to image the consistency or otherwise of orientation of white matter tracts. It is therefore of most value in the

Fig. 3.6 Coronal T2-weighted sequence (a) and transverse FLAIR (b) showing hyperintensity and swelling of the left hippocampus (on the right of both images) and white matter oedema in the left parahippocampal gyrus. Scans are of a 32-year-old woman presenting with tonic-clonic seizures, diagnosed with voltage-gated potassium channel autoantibodies (non-neoplastic limbic encephalitis); 6 months after presentation the patient had some verbal and autobiographical memory impairment and showed atrophy of the left hippocampus. (From Fauser *et al.* 2005 with permission.)

investigation of white matter disease, including demyelination. Tractography is the rendering of information on white matter tract orientation and shape in three dimensions. The technique can be used to produce beautiful anatomical displays that expose the structural underpinnings for functional connectivity in the brain and has much promise in neuropsychiatric disorders where aberrant development is the presumed pathogenesis (Catani & ffytche 2005).

Magnetisation transfer (MT) refers to the magnetisation of hydrogen bonds bound to macromolecules such as cell membranes. A pulse is applied that results in the exchange of magnetisation between bound protons and free water protons. Signal intensity is reduced at the site where the transfer occurred. The upshot of this technique is to increase the contrast of liquids versus solids and is thus used to image the cerebral vasculature (including distal vessels) in magnetic resonance angiography (MRA), usually in conjunction with gadolinium contrast enhancement (Castillo & Mukherji 2001).

An outstanding feature of MRI is the exquisite level of soft tissue contrast obtained by scanning in the IR sequence (T1-weighted images). Grey and white matter are strongly differentiated, yielding fine anatomical detail. The cortical grey matter is shown clearly and the thalami and basal ganglia are demarcated from the surrounding white matter and ventricular system. Sagittal scans show the corpus callosum, the columns of the fornix and the brainstem. In the posterior fossa, the substantia nigra and the middle cerebral peduncles can be discerned.

MRI holds several pronounced advantages over CT. Improved detection of small demyelinating lesions is coupled with excellent visualisation of the posterior fossa and pituitary regions, since there is little or no bone artefact to intrude on the images obtained. The various scanning sequences available give versatility of choice, and the slices to be viewed are readily switched from transverse to coronal or sagittal planes without disturbing or moving the patient.

MRI's superiority over CT has emerged in many clinical settings: in the detection of cerebral tumours, small infarcts and other vascular disease of the brain, and in revealing the lesions responsible for epilepsy (Fig. 3.7). It is very much better at showing the residua of cerebral trauma (Chapter 8) and in the detection of cerebral infections including those due to HIV/AIDS (Chapter 7). MRI has produced a new diagnostic sign, the pulvinar sign (increased signal intensity on T2-weighted images), found in variant CJD (Fig. 3.8). FLAIR sequences are also of value in variant CJD, showing hyperintensity of the pulvinar and dorsomedial nuclei of the thalamus, the so-called hockey-stick sign (Zeidler *et al.* 2000). The value of MRI in relation to the dementias and other neurodegenerative disorders is described in the appropriate sections of this book but the regional atrophy that characterises the frontotemporal dementias is easily visualised with MRI (Cooper & Greene 2005) (Fig. 3.9). Routine examination may be supplemented by the intravenous administration of a paramagnetic contrast agent (gadolinium bound to the chelating agent diethylene triaminepentaacetic acid), which yields additional information about derangements of the blood-brain barrier in the vicinity of lesions. This can be valuable in the context of vascular disease and in distinguishing a tumour from the oedema that surrounds it. Developments in MRA have been noted above (Bradley 1992).

Fig. 3.7 A 55-year-old woman with a 2-year history of increasing self-neglect and deteriorating function at work, followed by acute onset of paranoid psychosis and unsteadiness. (a) CT without contrast and (b) CT with contrast, both showing large frontal meningioma with contrast enhancement. (c) T1-weighted MRI with contrast and (d) T2-weighted MRI showing meningioma plus right frontal infarction, presumed to be related to acute deterioration.

Fig. 3.8 The pulvinar sign in a histopathologically confirmed case of variant Creutzfeldt–Jakob disease. (a) T2-weighted axial MRI showing high signal in pulvinar of the thalamus (arrows). (b) Changes were consistently conspicuous on proton density-weighted images. (From Zeidler *et al.* 2000 with permission.)

Fig. 3.9 Axial MRI showing abnormalities in the spectrum of frontotemporal lobar degeneration. Frontotemporal dementia is associated with frontal and temporal atrophy. Progressive non-fluent aphasia typically presents with left-sided perisylvian atrophy, whereas semantic dementia is characterised by left-sided anterior temporal lobe atrophy. (From Van der Flier & Scheltens 2005 with permission of BMJ Publishing Group Ltd.)

Fig. 3.10 Serially acquired T1-weighted MR scans from an initially asymptomatic patient destined to develop familial Alzheimer's disease. Scans were acquired over 4 years before criteria for dementia were met; the first symptoms were reported between scans (d) and (e). Each scan has been positionally registered to the baseline scan. See also Plate 3.2. (From Fox & Schott 2004 with permission.)

In all these settings MRI has the added advantage that repeat examinations are possible without hazard from radiation exposure. Use in relation to normal ageing and the diagnosis of Alzheimer's disease is an important clinical topic. It has been estimated that annual rates of cerebral atrophy are in the region of 0.2–0.5% in middle-aged healthy controls, rising to 3–5% at 70–80 years of age. This compares with rates of about 2–3% in Alzheimer's disease (Fox & Schott 2004). A 6-year longitudinal study showed that medial temporal lobe atrophy could be used to predict future cognitive decline in 45 participants aged over 60 years, with 91% specificity and 89% sensitivity (Rusinek *et al.* 2003) (Fig. 3.10: see also Plate 3.2). Schott *et al.* (2005) have used a method to coregister scans from individuals for the purposes of longitudinal comparisons using an automated technique known as the boundary shift integral method. They showed that this technique enabled more precise measurement of change. Changes in ventricular size – a 1-mL decrease in brain volume in Alzheimer's disease is on average accompanied by about 0.22 mL of ventricular expansion – showed even greater reliability. Presymptomatic change and progression are also visible on MRI in conditions such as Huntington's disease (Fig. 3.11).

With regard to safety of MRI, no adverse effects have been encountered, provided that patients with intracranial metallic foreign bodies, including aneurysmal clips, are excluded (the principal risk being the induction of heating in large metal objects such as skull prostheses), likewise patients with cochlear implants or cardiac pacemakers. Other potential exclusion criteria are discussed by Moseley (1994). Apart from feelings of claustrophobia and the noise of the machine (requiring ear protection), which some patients find distressing, the examination is without discomfort. Obese patients and those unable to lie still for several minutes may be better investigated with CT.

White matter hyperintensities

These are an example of an MRI-detected pathology, best seen on conventional dual-echo or T2-weighted images, or FLAIR sequences. They are frequently observed in the elderly but when multiple and confluent have definite pathological significance, being associated with increased risk of cerebrovascular and cardiovascular incidents, cognitive decline and depression (Launer 2003; Kales *et al.* 2005). Pathologically, the lesions show rarefaction of myelin sheaths and gliosis and are associated with microvascular

Fig. 3.11 Coronal T1-weighted inversion-recovery turbo spin-echo MRI: (a) healthy control subject; (b) Huntington's disease carrier with stage 2 disease showing thinning of the head of the caudate nucleus (white arrow) and the putamen (black arrow). (From Mascalchi *et al.* 2004 with permission.)

Fig. 3.12 T2-weighted MR scans showing punctate (Grade 1), early confluent (Grade 2), and confluent (Grade 3) white matter hyperintensities. Grade 2 and 3 lesions have been shown histopathologically to be associated with microangiopathy. (From Kapeller *et al.* 2004 with permission.)

abnormalities. Taking their usually periventricular distribution into account, ischaemic injury from compromise to penetrating arterioles is a likely aetiology (Lee & Marcus 2006); similar pathology is seen in the brains of depressed patients with periventricular and deep white matter hyperintensities (WMHs) but with less emphasis on vascular occlusion, pointing perhaps towards hypotensive mechanisms. A frontal location was particularly associated with depression (Thomas *et al.* 2002). Similarly, 'silent' brain infarcts, revealed by MRI, confer a more than twofold increased risk of demen-

tia and fivefold risk of stroke, discovered over periods of 3–4 years in the landmark Rotterdam study of over 1000 apparently healthy 60- to 90-year-olds (Vermeer *et al.* 2003). Based on MRI appearances, WMHs can be classified as punctate (grade 1), patchy or beginning of confluence (grade 2), and confluent (grade 3). Periventricular hyperintensities may appear as caps around the frontal or posterior horns of the lateral ventricles (grade 1), bands along the lateral ventricles (grade 2), and irregular changes extending into deep white matter (grade 3) (Fig. 3.12) (Kapeller *et al.* 2004). For

epidemiological research purposes the Rotterdam group rated the number and size of subcortical white matter lesions: small (<3 mm), medium (3–10 mm), and large (>10 mm). Periventricular white matter lesions were rated semiquantitatively per region: adjacent to frontal horn (frontal capping), adjacent to lateral wall of lateral ventricles, and occipital capping on a scale of 0 (no lesions), 1 (pencil thin periventricular lining), 2 (smooth halo or thick lining), or 3 (large confluent lesions). This was done for both hemispheres. The overall degree of periventricular white matter lesions was calculated by adding the scores for the three separate categories (range 0–9). A clear effect of ‘normal’ ageing can be seen in the graph (Fig. 3.13). This must be taken into account when judging whether a scan showing WMH is abnormal, and requires further investigation, or not. De Leeuw *et al.* (2001) found that in those aged over 60 years only 8% were free of subcortical white matter lesions, 20% had no periventricular white matter lesions and 5% had no white matter lesions in either location. Of subjects aged between 60 and 70 years, about 13% were completely free of subcortical white matter lesions and 32% were free of periventricular white matter

Fig. 3.13 Distribution of periventricular white matter lesions by 10-year age category. Note that the distribution of all subcortical white matter lesions is quite different showing marked skew with a peak around a mean score of 1 for all age groups. (From de Leeuw *et al.* 2001 with permission.)

lesions, whereas for subjects aged between 80 and 90 years these percentages were 0 and 5, respectively.

A related pathology is punctate foci of signal loss on conventional T2 images, corresponding to microscopic intracerebral bleeds associated with hypertension. This can be highlighted with T2*-weighted images, which show focal deposits of haemosiderin as dark spots (Fig. 3.14) (Kapeller *et al.* 2004). Such lesions may also be seen in cerebral amyloid angiopathy and in cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy (CADASIL).

Magnetic resonance spectroscopy

Magnetic resonance spectroscopy (MRS) is an important extension of MRI, in effect yielding information about certain chemical constituents of tissues. It depends on the principle that in a given magnetic field each distinct nuclear species spins at a unique frequency (Larmor frequency) that is altered slightly according to the chemical compound containing the element. This effect is called the *chemical shift*. When tissue within a static magnetic field is exposed to another competing field, by applying a radiofrequency pulse tuned to the Larmor frequency of the element in question, a spectrum can be obtained that reflects the various compounds in which the element is incorporated. By examining the spectrum the relative ratios of these components one to

Fig. 3.14 T2*-weighted MRI scan showing microangiopathy-related haemosiderin deposits. (From Kapeller *et al.* 2004 with permission.)

another can be calculated. The biochemical information is necessarily obtained at the expense of spatial information, although techniques are available which seek a compromise between the two.

Technical details are described by Keshavan (1993) and Maier (1995), including applications of relevance for neuropsychiatry. In essence the patient is placed in an MRI scanner of strong magnetic capability (1.5 T or above) and a radiofrequency coil is centred over the area of the head to be sampled. By appropriate tuning of the coil, spectra can be obtained that reflect the hydrogen nucleus (^1H) or the phosphorus nucleus (^{31}P). A range of other nuclei are also accessible (^{19}F , ^{13}C , ^{23}Na , ^7Li), but for technical reasons have been less explored.

^1H MRS yields spectra representing the tissue content of water, choline, creatine, lactate and *N*-acetyl aspartate (NAA), also smaller peaks derived from amino acids such as glutamate and aspartate. The water peak must be suppressed by appropriate techniques to prevent it from overriding the others. ^1H MRS thus gives information about the metabolic status of amino acids, neurotransmitters and their derivatives. In addition, it has potential for investigating histological change, in that NAA appears to be located entirely within neurones and their processes. Van der Knaap *et al.* (1992) have shown that in cerebral degenerative conditions the ratio of NAA to creatine falls as the severity of neuronal damage increases, this sometimes being evident before structural change is demonstrable. With astrocytosis the relative concentrations of choline and creatine are increased, while creatine falls with membrane breakdown.

^1H MRS has been studied in relation to multiple sclerosis, epilepsy, inborn errors of metabolism and cerebrovascular disorders. In schizophrenia, Maier *et al.* (1995) have shown significant reductions of NAA, creatine and choline in the left hippocampus, with smaller losses on the right. Buckley *et al.* (1994) have detected decreases in NAA in the frontal cortex in schizophrenia patients. Decreases in glutamate and aspartate have also been found in the dorsolateral prefrontal cortex, indicative of early neuronal degeneration (Stanley *et al.* 1992, 1993).

^{31}P MRS yields spectra of particular relevance to impaired energy metabolism, showing peaks for adenosine triphosphate (ATP), phosphocreatine (PCr) and inorganic phosphate (Pi). Ratios of ATP and PCr to Pi provide a measure of tissue health, varying with ischaemia, metabolic disorders and drug therapy. ^{31}P resonances can also reflect membrane metabolism by revealing peaks for phosphomonoesters and diesters. ^{31}P MRS has been employed to study brain anoxia, trauma and demyelination, as well as Alzheimer's disease and AIDS dementia. In schizophrenia evidence has been obtained of metabolic hypoactivity and disturbed membrane phospholipid metabolism in the dorsolateral prefrontal cortex.

Other promising areas for neuropsychiatric research include the use of MRS to detect inborn errors of metabolism in which metabolic by-products accumulate in the brain; ^{19}F MRS for the study of fluorine-containing antipsychotics such as trifluoperazine and fluphenazine; and ^7Li MRS for follow-

ing the pharmacokinetics of lithium (Keshavan *et al.* 1991). The labelling of glucose with ^{13}C has potential for brain metabolic investigations, and ^{23}Na MRS for differentiating the intracellular and extracellular pools of sodium. An excellent review of applications in psychiatry is provided by Malhi *et al.* (2002).

Functional magnetic resonance imaging

This still more recent development consists of ultra-fast imaging, whereby minute changes in regional cerebral blood flow can be detected and related to physiological activity occurring locally in the cortex. Brain changes can be charted in response to sensorimotor or cognitive activities, and it is possible even to capture alterations occurring with subjective events such as hallucinatory experiences (see later in section). Thus functional magnetic resonance imaging (fMRI) is a technique that can integrate structure with function by providing high-resolution mapping of the brain areas involved in discrete tasks and activities. Its promise for neuropsychiatry was spotted early (Binder & Rao 1994; David *et al.* 1994). Two main methods are used: fast low-angle shot (FLASH) and echoplanar imaging (EPI). FLASH depends on extremely brief intervals between successive radiofrequency pulses (5–15 ms), coupled with narrow 'flip angles' so that the proton nuclei return quickly towards their previous state of equilibrium. The resulting free induction decay images reveal any transient alterations of blood flow that occur. The EPI technique involves the encoding of free induction decay following a single radiofrequency excitation pulse, while a rapidly oscillating gradient is applied to generate a train of closely spaced signals from the tissue (gradient echoes).

Earlier studies used gadolinium enhancement, which increases the decay rate of the MRI signal (Belliveau *et al.* 1991), but Kwong *et al.* (1992) showed that it was possible to exploit the magnetic properties of haemoglobin when it changes from the oxyhaemoglobin to the deoxyhaemoglobin state (blood oxygenation-level-dependent contrast imaging or BOLD) (Ogawa *et al.* 1992). Changes in the relative proportions of oxyhaemoglobin and deoxyhaemoglobin, in response to local neuronal activity and the ensuing increased local blood flow, increases the relaxation time ($T2^*$ parameter), leading to a brightening of the magnetic resonance image in active regions. This completely non-invasive method of imaging transient changes in blood flow has obvious advantages over its precursors.

The earliest application of fMRI was in calcarine cortex activation in response to photic stimulation or checkerboard presentations, where the signal change may be around 2% or more; activation of contralateral and to some extent ipsilateral sensorimotor cortex on touching fingers to thumb; and activation of areas similar to those found with positron emission tomography (PET) on repetition of nouns and generation of verbs. Passive word listening activates the superior temporal gyri, especially on the left, and pattern recognition

memory activates areas within the medial temporal and frontal lobes. The technique is used to study the cerebral correlates of auditory hallucinations in schizophrenia, as abnormal moods, compulsions, and specific fears have similarly proved tractable to fMRI research. Analytic and image acquisition has improved year on year to enable 'signals' of less than 1% to be distinguished from noise, so that the most subtle of mental states and cognitive processes, including for example recollective experience, regret, sexual attraction and moral outrage, can all be shown to have their own functional anatomy. Certain advantages are evident for fMRI over PET as an avenue for further studies, notably much higher resolution with fine localisation, and the ability to track cortical responses as brief as 1 second or less. The non-invasiveness of the procedure and its lack of radiation exposure readily permit repeat examinations and hence the mapping of developmental and degenerative processes. Disadvantages include the difficulty of adapting task paradigms to the restricted space available while the patient lies within the scanner and also the degree of signal 'drop-out' in certain regions of the brain due to magnetic susceptibility differences such as where brain is close to air-filled bone cavities such as the temporal lobes and inferior frontal lobes (Matthews & Jezzard 2004). These artefacts may be worsened at higher field strengths.

Despite the huge impact fMRI has had on cognitive neuroscience, so far its clinical applications have been limited. This is probably due to the sensitivity of the method, which tends to reduce test-retest reliability, and the reliance on computationally intensive post-processing to deal with movement artefacts and low signal to noise and in the selection of the appropriate task contrasts. After all, the technique is about brain function and is semiquantitative so only yields meaningful information in response to questions framed as follows: What is the brain doing when subject A is carrying out task *x* compared with task *y*, and is this different in subject

B? fMRI in a single case, as required for clinical utility, is certainly feasible but most research relies on averaging across subjects and mapping onto a standard neuroanatomical brain space (rather than a person's actual brain). fMRI brain images may not align perfectly with structural images. Nevertheless, one application of fMRI likely to increase is lateralisation of language functions in pre-epilepsy surgery assessment since it is far less invasive than the Wada procedure (see Chapter 2) yet yields consistent results (Fig. 3.15: see also Plate 3.3). Localising eloquent cortex and indeed ictal activity in such patients is also possible with fMRI and much effort is being expended into integrating imaging across modalities, by using EEG or MEG concurrently or sequentially in the same patient (Matthews & Jezzard 2004). Obviously each technique has its own time window and none measures exactly the same phenomena. The future is bound to see the increasing use of fMRI in the early diagnosis and response to treatment of cognitive disorders and in the mapping of functional reorganisation after brain injury or stroke.

Positron emission tomography

PET is restricted to special centres, since a cyclotron must be close at hand for the manufacture of the short-lived isotopes involved. In essence, PET produces a cross-sectional image of brain radioactivity after the injection of a suitably labelled compound, yielding information about the site and rate of dynamic processes such as cerebral blood flow and metabolism. The principal value of the technique is its ability to reveal aspects of regional brain metabolism that are not otherwise accessible to study.

The principles involved are outlined by Bench *et al.* (1990) and Watson (1991). Compounds labelled with short-lived isotopes, for example ^{18}F or ^{15}O , are injected or inhaled and allowed to reach a

Fig. 3.15 Functional magnetic resonance imaging: differences in relative language lateralisation for a verbal fluency task can be found between patients with right or left temporal lobe epilepsy (TLE). Illustrative activation maps are shown here, co-registered with individual high-resolution structural MRI. Cluster detection was carried out on all voxels above $z = 2.3$ to determine clusters significantly activated (corrected $P < 0.01$) in the experimental task condition. The patient with right TLE has predominantly left hemisphere activation. In contrast, the activation map for the patient with left TLE shows bihemispheric activations. See also Plate 3.3. (From Matthews & Jezzard 2004 with permission.)

steady state in the tissues. The excess of protons over neutrons in such isotopes confers instability, leading to the emission of positrons (positively charged electrons). With the discharge of a positron, one of the protons in the nucleus becomes a neutron and stability is achieved again. An emitted positron has a range of only a few millimetres in the tissues before it encounters an ordinary electron and the two then annihilate each other. Their mass is converted into two gamma rays, which originate simultaneously and propagate in almost precisely opposite directions. This allows their point of origin to be determined by 'coincidence counting' with suitably placed detectors, and this point of origin will be very close to the point where the positron was released. Hence paired detectors arranged around the head can be used to compute the distribution of the isotope with a fair degree of accuracy. Algorithms similar to those used in CT can yield a visual image of its location within the brain. With the introduction of both single photon emission computed tomography (SPECT)/CT and PET/CT, multimodality imaging has entered routine clinical practice in some specialist centres, particularly in relation to neuro-oncology. Multiple slice spiral CT scanners have been incorporated with multiple detector gamma cameras or PET systems, allowing integration of structural and functional information on the same patient at the same time (Eli 2006).

The analysis of PET scan data using radiolabelled water, like fMRI, can be immensely complex, requiring numerous comparisons and the generation of extensive statistical data. In the identification of regional changes in blood flow, for example, regional shifts must be 'normalised' against global reductions elsewhere. Where activation paradigms are employed to assess changes in metabolism or blood flow consequent on cognitive or other activity, special care must be taken in this regard. 'Subtraction' techniques, whereby images generated in a given subject are compared while at rest and when engaged in some specific activity, were developed for PET and have now been adopted for fMRI. Similar methods have been developed for comparisons between different groups of subjects; the subtraction of common activity again allows display of an image that represents statistically significant differences on a pixel-by-pixel basis (statistical parametric maps) (Friston *et al.* 1991). fMRI has taken over from PET as the main tool of human cognitive neuroscience especially in healthy participants, since the need for radiopharmaceuticals and intravenous or intra-arterial injection is avoided completely. Breakthroughs derived from PET studies in explicating the functional anatomy of complex sensory and cognitive processes in living humans (Haxby *et al.* 1991; Zeki *et al.* 1991) set the benchmark for fMRI, where findings have been largely replicated and extended.

The isotopes chiefly used are ^{15}O , ^{13}N , ^{11}C and ^{18}F , which have half-lives of approximately 2, 10, 20 and 110 minutes, respectively. ^{15}O may be inhaled and the arterial blood sampled to yield quantitative measurements of regional cerebral blood flow and regional cerebral oxygen utilisation. Alternatively, a bolus of ^{15}O -labelled water may be injected intravenously to obtain brief repeated images of cerebral blood flow, which serve as a marker of neuronal activity. ^{18}F may be incorporated into 2-deoxy-D-glucose (^{18}F -fluorodeoxyglucose or FDG), which is injected to measure local glucose metabolic rates. The compound enters the brain as though it were glucose, but cannot be degraded and remains trapped within the cells for several hours. Estimates of regional glucose utilisation can therefore be made by repeated venous sampling in conjunction with the scan. ^{11}C may be incorporated into deoxyglucose for similar purposes. The regional metabolic rate for glucose correlates strongly with synaptic activity.

The important PET studies carried out in relation to diseases and syndromes will be noted in their respective chapters. A useful recent monograph on the clinical and research uses of PET of relevance to neuropsychiatry, including Alzheimer's disease, movement disorders, depression and schizophrenia, is provided by Meltzer (2003), and Smith *et al.* (2003) also review applications of PET in these conditions plus anxiety disorders and obsessive-compulsive disorder.

PET studies with cerebral activation

PET can be used in two main ways. First, it can measure cerebral activity, inferred from changes in regional cerebral blood flow using radiolabelled water or regional cerebral metabolism using FDG. The other main use is to map the distribution of a physiologically relevant molecule or macromolecule (e.g. neurotransmitter, receptor or transporter) using radioligands (Pilowsky 1996). This may be used to elucidate disease mechanisms, to map degeneration in a group of pharmacologically active cells or to assist in pharmacotherapy. The first use is declining as a research tool but has a clearly defined clinical role in neuropsychiatry in the investigation of the dementias and movement disorders in particular. The second use is expanding as the chemical pathologies of disorders become better understood aided by the promise of novel drug development.

In Alzheimer's disease, the regional metabolic rate for glucose is reduced throughout the brain but particularly in the temporoparietal region, which may show 50% reductions in severe cases (Fig. 3.16: see also Plate 3.4);

Fig. 3.16 Fluorodeoxyglucose positron emission tomography images in Alzheimer's disease: (left) normal brain; (right) Alzheimer's brain. Arrows point to area of posterior hypometabolism. See also Plate 3.4. Available at http://www.uhseastpescan.com/zportal/portals/pat/brain/Alzheimers_Disease/pet_scans

frontotemporal dementias will tend to show the expected region-specific hypometabolism (Newberg *et al.* 2002). However, given the variations in normal ageing, PET cannot claim to be a diagnostic test at present. Early studies of Parkinson's disease indicated basal ganglia hypermetabolism against a background of general hypometabolism, especially in cases with cognitive impairment. These changes tend not to be reversible with standard treatment but are with successful fetal cell transplant. Hypometabolism in the caudate is a consistent finding in Huntington's disease. FDG-PET will show hypermetabolism in the region of an epileptic focus during seizures in up to 70% of cases and hypometabolism interictally in up to 80% (Newberg *et al.* 2002). Studies using PET (and SPECT, see later in chapter) have been able to demonstrate uncoupling of blood flow and metabolism following stroke, where blood flow may be disproportionately increased ('luxury' perfusion) or reduced ('misery' perfusion). Hence PET may be useful clinically in providing at least part of the explanation why a patient with a comparatively small structural lesion may nevertheless have profound deficits (Blake *et al.* 2003).

Radioligands and psychopharmacology

Most interest has centred on the dopaminergic system, in relation for example to movement disorders and schizophrenia as described in Chapters 12 and 2.

Postsynaptic D_2 receptors can be studied using raclopride labelled with ^{11}C . Presynaptic function is examined with ^{18}F -dopa which detects dopamine stores in nerve terminals, and with ^{11}C -nomifensine which labels presynaptic reuptake sites. The radiolabelled ligands include ^{11}C -flumazenil for central benzodiazepine receptors, ^{11}C -carfentanil for opiate receptors, ^{11}C -dextemide for muscarinic cholinergic receptors, and ^{11}C -deprenyl for monoamine oxidase B. ^{11}C -*N*-methylpiperone binds to both D_2 and S_2 receptors, but the reversibility of its binding in the cortex can provide an index of serotonergic function there, although there are now radiotracers for 5-hydroxytryptamine receptors ($5HT_{2A}$) and transporters. Complex tracer kinetic models are utilised in certain studies to reveal subtle changes in receptor numbers and affinity, especially in the investigation of psychiatric disorders.

PET can be used to examine the influx of drugs into brain tissue and assess their interaction with receptors, to monitor receptor blockade in relation to clinical effect, or to observe responsivity of distinct neurochemical pathways to pharmacological agonists and antagonists. This last may be combined with simultaneous cognitive activation in order to reveal more clearly the differences between patients and controls. Some drugs may be labelled directly, such as the neuroleptics pimozide and clozapine and the anticonvulsants valproate and diphenylhydantoin. After injection in tracer amounts their distribution within the brain can be studied directly, also their affinities at specific receptor sites. Studies in relation to the neuroleptic treatment of schizophrenia are reviewed by List and Cleghorn (1993), with a

more recent update provided by Frankle and Laruelle (2002). PET has been used to show the rapidity of D_2 receptor blockade in the striatum on commencing neuroleptics, and the time course of reversal of the blockade when they are discontinued. It has been suggested that rapid dissociation rates of binding to the D_2 receptor may underlie the low level of extrapyramidal side effects seen with the atypical antipsychotics. Dose-dependent relationships have been demonstrated between serum levels of neuroleptics and the degree of inhibition of striatal D_2 binding, and attempts have been made to detect differences in patients who are resistant to neuroleptic effects. Differences between typical and atypical antipsychotics have also been studied in this manner as well as 'regional selectivity' of effect, i.e. striatal versus extrapyramidal (Erritzoe *et al.* 2003).

Other molecules that may be labelled include amino acids, fatty acids, alcohols and sugars. A considerable variety of active metabolic processes are thus accessible to study.

PET in Parkinson's disease

Dopamine and dopaminergic neurones are central to the pathophysiology of Parkinson's disease. Applications of PET in the investigation of movement disorders is well reviewed by Piccini and Whone (2004), summarised below. Such neurones are susceptible to tagging by positron-emitting isotopes. This may involve the dopamine transporter (responsible for reuptake from the synaptic cleft), the vesicular monoamine transporter (VMAT)-2 (responsible for packaging dopamine into the synaptic vesicles), and the enzyme aromatic amino acid decarboxylase (responsible for transforming dopa to dopamine), which is located inside the synaptic terminal (Piccini & Whone 2004). The most extensively studied ligand in Parkinson's disease is ^{18}F -dopa which, as stated above, reflects predominantly presynaptic nigrostriatal activity. ^{18}F -Dopa shows reduced accumulation in the putamen, particularly the caudal region, in Parkinson's disease, and its distribution is frequently asymmetrical. Other parkinsonian syndromes may see similar reductions but not those of vascular origin. Essential tremor does not affect ^{18}F -dopa binding in the striatum (Fig. 3.17: see also Plate 3.5) (Brooks & Piccini 2006). The advantage of using radiotracers that interact with processes central to dopaminergic neurotransmission rather than those that act as direct measures of dopamine receptor occupancy (e.g. ^{11}C -raclopride) is that they are not so distorted by dopaminergic therapy and so may be more stable markers of disease (Brooks *et al.* 2003). D_2 binding is increased early in untreated Parkinson's disease.

Dopamine transporter ligands include ^{11}C -methylphenidate and the cocaine analogues ^{11}C - β -3 β -(4-fluorophenyl) tropane (for PET) and ^{123}I - β -3 β -(4-iodophenyl) tropane (CIT; for SPECT). Almost the entire VMAT-2 signal in the striatum is attributable to dopaminergic vesicular binding. Denervation is reflected in marked reductions in signal using the

Fig. 3.17 Striatal uptake of dopamine transporter (DAT) ^{11}C -RTI-32, ^{123}I - β -CIT, $^{99\text{m}}\text{Tc}$ -TRODAT, vesicular monoamine transporter (VMAT2) ^{11}C -DTBZ, and dopa decarboxylase (DDC) ^{18}F -dopa in a healthy control subject and a patient with early Parkinson's disease (PD). In PD the putamens are targeted asymmetrically. See also Plate 3.5. (From Brooks & Piccini 2006 with permission.)

ligand ^{11}C -dihydrotetrabenazine (DTBZ), even in the early stages of Parkinson's disease and this is not affected by medication or disease-related compensatory changes (Bohnen & Frey 2003). ^{11}C -RTI-32 is an *in vivo* marker of both dopamine and noradrenaline (norepinephrine) transporter binding. In a small study in Parkinson's disease, anxiety inversely correlated with the binding in the limbic system including the anterior cingulate cortex, thalamus, amygdala and ventral striatum while apathy was inversely correlated with binding in the ventral striatum. The results suggest that depression and anxiety in Parkinson's disease may be associated with regionally specific loss of dopamine and noradrenaline innervation and that work in Parkinson's disease may have wide implications for the understanding of other neuropsychiatric disorders (Brooks & Piccini 2006).

Single photon emission computed tomography

SPECT has come into prominence more recently than PET, although in some respects its origins go back further. It is essentially an elaboration of radioisotope scanning brought about by the harnessing of computer technology analogous to that used in CT for reconstructing images of the brain. Though considerably less accurate than PET, and a good deal less amenable to quantitation, the images obtained with the most modern machines can be of remarkable quality (Fig. 3.18: see also Plate 3.6). Since the radioisotopes employed have much longer half-lives than those used for PET, there is no requirement to have a cyclotron close at hand. This accounts in large measure for the increasing attention devoted to the technique. SPECT can be available at any hospital where there is a nuclear medicine facility, and its greatly reduced cost in comparison with PET means that larger samples may be investigated and that it can be applied more readily in a clinical context. However, the range of normal variation encountered is considerable.

The procedure involves the administration of radiopharmaceuticals that emit not positrons but gamma rays (photons) directly. The tracers are taken up into the brain, and their regional concentration detected by focused collimators arranged around the head or by a rotating gamma camera. At each point the detector samples a cone of brain tissue, brain images then being obtained by summation according to the standard tomographic technique. Since the gamma rays are emitted directly from the radiotracers employed, there is no annihilation process as with PET. Coincidence counting is therefore precluded and the points of origin of the gamma rays are simply determined from their trajectories, consequently with less precision. Nevertheless, resolution approaches 8–10 mm with the most recent systems (cf. 5–7 mm with PET).

The tracers most frequently used are markers of cerebral blood flow. Glucose and oxygen uptake cannot be revealed directly by SPECT, but will normally be closely coupled to blood flow in the situations where SPECT is employed. With the continued development of tracer biochemistry, methods are also available for imaging a variety of neurotransmitters and their receptor sites as described below.

Xenon-133 (with a half-life of 5.3 days) may be administered by inhalation or injection for cerebral blood flow studies. Cerebral blood flow may then be measured without arterial blood sampling. However, isopropylamphetamine (IMP) labelled with ^{123}I is simpler to use. It has a half-life of 13 hours, and being lipophilic it penetrates brain tissue and becomes trapped within it, revealing patterns of distribution of blood flow that remain stable over a substantial period of time. Scanning is carried out after a single intravenous injection; higher resolution is obtained than with xenon but at the expense of longer scanning times. IMP has now been superseded by hexamethylpropyleneamine-oxine (HMPAO) labelled with technetium-99m ($^{99\text{m}}\text{Tc}$), which is similarly lipophilic but has a shorter half-life (6 hours) and thus can be given in higher dosage, yielding improved definition and shorter scanning times. $^{99\text{m}}\text{Tc}$ is routinely available and can be obtained from a molybdenum-99 'generator' which has a shelf-life of 67 hours. The HMPAO is taken up in the brain in proportion to blood flow within a few minutes, yielding a 'frozen image' that remains stable for several hours. Scanning is normally undertaken some 20–30 minutes after injection. $^{99\text{m}}\text{Tc}$ -labelled ethyl cysteinate dimer (ECD) is similar but is more stable *in vitro*.

Fig. 3.18 An HMPAO-SPECT scan from a normal subject, using a Strichman Medical Equipment multislice, head-dedicated scanner. The slices are orientated parallel to the orbitomeatal plane. See also Plate 3.6. (Courtesy of the Department of Nuclear Medicine, King's College Hospital, London.)

SPECT has proved of clinical value in relation to strokes, and for the investigation of blood flow during migraine attacks. In the dementias, it can reveal the reductions of uptake in the temporoparietal regions typical of Alzheimer's disease, and has been used to demarcate the contrasting group of frontal lobe dementias (see Chapter 2, under Cerebral lobe localization). Multi-infarct dementia may be indicated by scattered focal deficits (see Chapter 8). In Huntington's disease changes may be detected in the heads of the caudate nuclei (Blake *et al.* 2003). Applications in the field of epilepsy and alcoholism are described in their respective chapters.

In a retrospective evaluation of 20 neuropsychiatric patients suffering from dementia, amnesic states, depression and personality disorder, Trzepacz *et al.* (1992) have shown the value of IMP SPECT in revealing clinically relevant brain abnormalities. Studies in schizophrenic patients have revealed hypoperfusion frontally much as in PET studies, and decreased blood flow has been reported in depression with significant increases on recovery (Sackheim *et al.* 1990). Musalek *et al.* (1989) have reported distinctive patterns in patients with auditory and tactile hallucinations. McGuire *et al.* (1993) used a split-dose technique with technetium-labelled HMPAO to provide a

snapshot of brain function in patients experiencing auditory verbal hallucinations.

Neurotransmitter imaging

As with PET, SPECT make it possible to image certain neurotransmitter receptors. Most success has been achieved with the dopamine system: Crawley *et al.* (1986) used ^{77}Br -labelled spiperone and Pilowsky *et al.* (1994) iodobenzamide (IBZM) labelled with ^{123}I to explore D_2 receptor binding in a semi-quantitative manner. Quinuclidinyl-4-iodo-benzilate (QNB) labelled with ^{123}I may be used to detect muscarinic acetylcholine receptors, a decrease being revealed in the posterior temporal cortex in patients with Alzheimer's dementia (Holman *et al.* 1985; Weinberger *et al.* 1991). Other potential ligands include raclopride for D_2 receptors, IBZP for D_1 receptors and flumazenil for benzodiazepine receptors, all labelled with ^{123}I . As noted above, the dopamine transporter is amenable to SPECT radioimaging using ^{123}I - β -CIT, which can show 50% reductions at presentation. A fluoropropyl derivative has recently been developed, ^{123}I -FP-CIT, which has faster kinetics so that images can be acquired 3 hours after administration (compared with 24 hours) (Piccini & Whone

2004). Finally, ^{99m}Tc -TRODAT-1 is a convenient ligand for clinical use.

Other special investigations

Echoencephalography (ultrasound)

Echoencephalography is used to detect developmental anomalies of the brain and CNS *in utero* and in paediatric neurology (see Barnewolt & Estroff 2004 for review). It is a rapid procedure, without discomfort or risk to the patient.

Radioisotope scan (radionuclide scan, gamma encephalography)

Radioisotope scanning is a technique for the investigation of cerebral tumours and some cerebral infarctions. However, its use has declined very markedly since the introduction of CT and other scan procedures although it is still important where access to these is limited. An isotope preparation such as technetium-99 (^{99}Tc) is injected intravenously in a dose according to body weight. This is picked up by vascular tissue, especially neovascular tissue, and the gamma radiation may be detected by a 'scan' of the skull with radioactive counting equipment.

Isotope cisternography (isotope encephalography)

Isotope cisternography provides a means of obtaining a dynamic picture of the CSF circulation in conjunction with air encephalography in the investigation of patients with communicating hydrocephalus. Since the advent of CT and MRI its usefulness has declined. Visualisation of the morphology and the dynamics of the CSF circulation may be achieved by intrathecal injection of metrizamide in conjunction with a CT scan (Isherwood 1983). However, modern dynamic MRI techniques can detect CSF flow patterns non-invasively.

Cerebral angiography

Cerebral angiography consists of taking X-ray films in rapid succession after an injection of contrast medium into the cerebral circulation. Injection of the common carotid artery displays the internal carotid and its area of supply by way of the anterior and middle cerebral arteries, and sometimes the posterior cerebral arteries also. Vertebral arteriography is more hazardous, but can be used to outline the vertebral, basilar and posterior cerebral arteries.

Because of the hazards, angiography has now been supplanted by CT (see Computed tomography, earlier in chapter) as a screening procedure for tumours. Furthermore, a range of new CT angiography and MRI applications such as MRA provide subsecond temporal resolution and three-dimensional techniques are rapidly developing (Coley *et al.* 2003). These may be used for investigation of a range of cerebrovascular disorders, including aneurysms and malformations. The precise delineation of vascular anomalies may still require X-ray angiographic techniques.

Air encephalography (pneumoencephalography)

Before CT became available, air encephalography was a technique of great importance for visualising intracranial pathology. For a while a place remained for the technique in a small minority of patients, chiefly for visualising small basal tumours near the optic or auditory nerves or in the brainstem, and for clarifying obstructions in the aqueductal region. Such areas are relatively inaccessible on CT but are now well visualised by MRI. MRI has also displaced the use of air encephalography for the investigation of patients with temporal lobe epilepsy, since coronal views allow detailed visualisation of the temporal horns of the lateral ventricles.

Nerve conduction studies and electromyography

Nerve conduction studies (NCS) are frequently carried out alongside electromyography (EMG). These tests are usually carried out by a clinical neurophysiologist and require some skill in their interpretation. Their main role is in the diagnosis and monitoring of disorders of the peripheral nervous and neuromuscular systems. Useful overviews of their role in clinical practice are provided by Mallik and Weir (2005) and Mills (2005a,b). Interested readers should consult the appropriate neurophysiological texts for more information.

NCS involve the application of depolarising square wave electrical pulses to the skin over a peripheral nerve producing (i) a propagated nerve action potential recorded at a distant point over the same nerve; and (ii) a compound muscle action potential arising from activation of muscle fibres in a target muscle supplied by the nerve. In both cases these may be recorded with surface or needle electrodes. Surface electrodes are designed to give information about the whole of a muscle stimulated, providing data for the time taken for the fastest axons to conduct an impulse to the muscle and the size of the response. Needle electrodes for NCS give very accurate conduction time information, but because they record from only a small area of muscle or nerve, they give poor or, in the case of nerves, more complex information making numerical analysis difficult. However, needle recordings are most appropriate when severe muscle wasting has occurred, or when the depth of a muscle under study makes a surface recording impossible (quoted from Mallik & Weir 2005).

EMG can detect abnormalities such as chronic denervation or fasciculations in clinically normal muscle. It can, by determining the distribution of neurogenic abnormalities, differentiate focal nerve, plexus, or radicular pathology; it can also provide supportive evidence of the pathophysiology of peripheral neuropathy, either axonal degeneration or demyelination. EMG is an obligatory investigation in motor neurone disease to demonstrate the widespread denervation and fasciculation required for secure diagnosis. Recordings are made with a disposable concentric needle electrode inserted into the muscle. A fine wire in the axis of the needle is insulated from the shaft, the end of the needle being cut at an acute angle. The area of the recording surface determines the volume of muscle that the needle can 'see'. Conventional EMG needles record from a hemisphere with radius of about 1 mm. Within this volume there are some 100 muscle fibres. The many hundreds of muscle fibres belonging to one motor unit are distributed widely throughout the cross-section of the muscle, and therefore within the detection region of the needle there may be just four to six fibres of a single motor unit. Analysis of the waveforms and firing

rates of single motor or multiple motor units can give diagnostic information. Electromyographers are skilled at interpreting both the appearance of muscle activity and the sound of the activity transmitted through a loudspeaker. Normal resting muscle is silent (Mills 2005a).

Neurophysiology offers the most sensitive diagnostic tests for disorders of neuromuscular transmission. However, the tests are not absolutely specific. Repetitive nerve stimulation shows a decrementing response in myasthenia gravis, the decrement being more pronounced in proximal muscles. However, single-fibre EMG (SFEMG) is much more sensitive; SFEMG of facial muscles detects an abnormality in virtually all cases of myasthenia gravis. In Lambert-Eaton myasthenic syndrome, the compound muscle action potential evoked in hand muscles is small and increases dramatically after exercise. Decrement is seen on repetitive nerve stimulation, and stimulated SFEMG, if required, shows a frequency-dependent increase in jitter (Mills 2005b).

Since the peripheral nervous system may be affected as a component of a syndrome that also involves the CNS (e.g. toxic and metabolic disorders such as vitamin deficiencies and porphyria; peripheral and CNS demyelination as in multifocal leucoencephalopathy; degenerative disorders such as motor neurone disease; mitochondrial disorders affecting muscle and the CNS as in myoclonus epilepsy with ragged-red fibres) but is somewhat more accessible, such testing may be of great relevance to the neuropsychiatrist. NCS and EMG can clarify the causes of numbness, abnormal sensations, weakness, fatigue and muscle wasting, or at least help to exclude certain causes. This may be valuable in the investigation of conversion disorders and chronic fatigue syndromes. In the former, EMG may be combined with transcranial magnetic stimulation to demonstrate to the patient and clinician the integrity of the motor system or that 'the muscles and nerves are still working'. The main safety concern is the need for caution in patients with a cardiac pacemaker.

Appendix

Tests of perception

Bender-Gestalt Test (Bender Visual Motor Gestalt Test)

Bender produced what is primarily a copying test, independent of memory and learning ability, although it can be varied to examine reproduction from memory after a lapse of time if required.

Nine simple designs are presented to the subject, one at a time, and he is asked to copy them. The type and frequency of errors are noted, and serve as the basis for identifying neurotic, psychotic and brain-damaged subjects. Interpretation relies to a large extent on subjective intuitive procedures, but attempts have been made to standardise it for certain purposes.

It has been widely used as a rapid screening test, but the overlap between groups reduces its value when applied to the individual subject. Nevertheless its efficiency at detect-

ing brain damage has sometimes received surprisingly strong support compared with other long-established psychometric tests. Lezak (1995) reviews the now extensive literature of this simple test and the sometimes elaborate scoring procedures employed.

Visual Object and Space Perception Battery

Warrington and James (1991) have introduced a nine-test battery for exploring visual perception that can be given in parts or as a whole. Minimal motor response is required from the patient so that any praxic element is eliminated.

The first test screens for visual impairment, which might preclude proceeding further. A series of cards is shown with an all-over pattern and the patient must say which of them contains a degraded 'X'.

The next four tests show views of letters, animals or objects that have been rendered puzzling in various ways. In *Incomplete Letters*, the subject has to identify a series of randomly degraded letters. *Silhouettes* requires the subject to identify animals and inanimate objects depicted as black silhouettes and rotated through various degrees. In *Object Decision* the subject has to choose which of a group of silhouettes, again rotated, represents a real as opposed to an imaginary object. In *Progressive Silhouettes* the subject sees two series of silhouettes, each representing a single object, presented at a series of angles that gradually approach normality.

The final four tests deal with aspects of space perception. *Dot Counting* requires the subject to count the number of dots in a small array. In *Position Discrimination* the subject must decide which of two squares, presented side by side, has the dot exactly in the centre. *Number Location* consists of two squares one above the other; in the lower display there is a single dot, and the subject must say which number in the square above corresponds to its position. *Cube Analysis* requires the subject to count the number of cubes depicted in line drawings of three-dimensional displays.

Patients with right hemisphere lesions have been shown to perform less well than patients with left hemisphere lesions on all of these subtests.

Behavioural Inattention Test

This battery of tests is designed to examine unilateral visual neglect (Wilson *et al.* 1987). The first six subtests are traditional procedures for examining for neglect, and the next nine 'behavioural tests' aim to identify everyday problems likely to be faced by patients, thereby serving as a guide to rehabilitation.

The traditional tests include line crossing, letter cancellation, star cancellation, figure- and shape-copying tests, line bisection tests and free drawing of a clock, a man or woman and a butterfly.

The behavioural tests examine picture scanning, telephone dialling, menu reading, article reading, telling and setting the time on a clock face, coin sorting, address and sentence copying, map navigation and card sorting.

Halligan *et al.* (1991) have shown excellent test-retest reliabilities for the battery, and good correlations on each of the

two subsets with occupational therapists' reports and measures of activities of daily living.

Test of Everyday Attention

The Test of Everyday Attention (Robertson *et al.* 1994, 1996) assesses three aspects of attention: selective attention, sustained attention, and attentional switching. The materials relate to everyday situations, making this instrument ecologically plausible and acceptable to patients. It is said to be sensitive enough to show age effects in the normal population while also showing specific types of attention disorders in patients with various types of neurological disorders. The subtests include the following.

- Map Search: looking at a large colour map of Philadelphia, patients search for symbols (selective attention).
- Elevator Counting (with and without distraction): listening to a series of tones, patients are asked to indicate a specific floor level (sustained attention).
- Visual Elevator: attentional switching and cognitive flexibility is measured by asking patients to count up and down as they follow a series of visually presented 'floors' in the imagined elevator (also in a fixed speed version presented on audio tape).
- Telephone Search: while looking at a simulated telephone directory patients are asked to identify key symbols (also presented as a dual task test: while searching through the directory the patient is asked to simultaneously count tones presented on tape).
- Lottery: patients are asked to listen for their 'winning number' presented on audio tape, then write down the two letters preceding a specified number.

The Test of Everyday Attention consists of parallel versions yielding nine percentile scores that can be used to track recovery of function following brain damage. Administration time is 45–60 minutes. The normative sample, composed of 154 normal individuals ranging from 18 to 80 years of age, is stratified by age and education.

Language tests

Boston Naming Test

This consists of 60 line drawings of objects that the patient must name (Kaplan *et al.* 1983). The items range in difficulty from common objects such as a tree or pencil to more difficult ones like a sphinx or a trellis. When the subject cannot name the picture he is given cues, first a stimulus cue (e.g. 'it's something to eat'), then a phonemic cue (i.e. the opening sound of the word). These help to identify whether the subject knew the word at all. The number of cues needed is noted.

Normative data on the test are provided by Van Gorp *et al.* (1986). It effectively elicits naming impairments in patients with aphasia, but is also sensitive to the language difficulties of patients with dementia (Margolin *et al.* 1990). Edith Kaplan (quoted in Lezak 1995) has noted that patients with right hemisphere damage, especially right frontal damage, may show responses indicative of perceptual fragmentation, for

example identifying the mouth-piece of a harmonica as the line of windows on a bus.

Graded Naming Test

The subject is presented with 30 line drawings of items and asked to name them (McKenna & Warrington 1983). These vary with regard to frequency of usage and consequently in naming difficulty. It is possible to judge whether naming ability is in line with reading ability, as estimated by the NART or the Schonell Graded Word Reading Test, or with vocabulary scores as measured on the WAIS.

Token Test

De Renzi and Vignolo (1962) introduced a test especially sensitive to minor degrees of impairment of language comprehension. This can be of considerable value since routine examination often fails to detect slight receptive language disorder. Moreover a patient with aphasia may seem to have difficulties limited to verbal expression alone, and it can then be difficult to explore the more subtle aspects of language comprehension without taxing other cognitive functions as well.

The test uses a number of simple 'tokens' that are manipulated by the subject. He is given a series of verbal commands expressed in progressively more complex messages, in response to which he must perform simple manual tasks such as picking up, moving or touching the tokens. The tokens used are of two different shapes (circles and rectangles), two different sizes and five different colours. It is first necessary to ensure that the subject appreciates the meaning of circle and rectangle and that colour recognition is intact.

In the first part of the test the large circles and rectangles are displayed and the patient is asked to pick up each in turn by telling him to 'pick up the yellow rectangle', 'pick up the white circle', etc. Subsequent parts proceed in graded stages by introducing the small as well as the large tokens, by asking the subject to pick up two at a time, and by introducing more complex instructions that involve new grammatical elements. In the final part of the test, prepositions, conjunctions and adverbs are introduced so as to radically change the meaning of the action which the subject is required to perform. For example 'put the red circle on the green rectangle', 'touch the blue circle with the red rectangle', 'pick up all the rectangles except the yellow one', 'put the red circle between the yellow rectangle and the green rectangle', 'after picking up the green rectangle touch the white circle'.

Thus the test consists of messages that are conceptually elementary and short and easy to remember, but which make two kinds of demand on comprehension: the token must be identified by three independent features, and the subject must grasp the semantic complications which are later introduced. Deficits often become obvious only in the later stages of the test, and can then emerge clearly even among aphasics who have shown no evidence of difficulty with comprehension during normal conversation.

Boller and Vignolo (1966) found that the test was more impaired in aphasics than non-aphasics, as expected, but also that among non-aphasics it was more impaired by

left-sided brain damage than right. The latent sensory aphasia thus identified was independent of non-language impairments as measured by Raven's Progressive Matrices, and appeared not merely to be a consequence of impaired general intelligence. The test was shown to be more sensitive for the detection of mild comprehension deficits than Marie's Three Paper Test, which has been widely employed for this purpose (see Comprehension of speech).

Speed and Capacity of Language Processing Test

In the first part, the Speed of Comprehension Test, the rate of processing of language is measured (Baddeley *et al.* 1992). The subject is required to read a number of statements that vary in content and syntactic structure, putting a tick against those which are true or sensible and a cross if they are false or silly. The subject must work as quickly as possible through the series.

The second part, the Spot-the-Word Test, is introduced to control for poor verbal skills *per se*, rather than slowed information processing. In this test the subject is presented with 60 pairs of items, each consisting of a word and an invented non-word, and must indicate which of the pair is real. The extent to which the subject's speed of comprehension falls behind performance on the Spot-the-Word Test indicates how far language comprehension skills have been impaired.

The Spot-the-Word Test may have another value in itself, in that it has proved to be a potentially useful method for estimating premorbid intelligence. Thus it has been shown to correlate highly with verbal intelligence as estimated by Mill Hill Vocabulary scores or performance on the NART, and performance seems not to decline with age even in the presence of intellectual impairment (Baddeley *et al.* 1993). In performing the task a number of parallel routes are available for making the lexical decisions – the meaning of the word, its orthographic appearance, its sound, or a general feeling of familiarity – and this may be what makes it relatively resistant to brain damage.

Psycholinguistic Assessments of Language Processing in Aphasia

The Psycholinguistic Assessments of Language Processing in Aphasia (PALPA) (Kay *et al.* 1992) consists of 60 tests of components of language structure such as orthography and phonology, word and picture semantics and morphology and syntax. The tests make use of simple procedures such as lexical decision, repetition and picture naming and have been designed to assess spoken and written input and output modalities. Guides are included that help to suggest which selection of test may be appropriate for each aphasic person.

Memory tests

Paired associate learning test

Paired associate learning involves mastery of the appropriate response when the first member of a pair of words is presented. It forms part of the Wechsler Memory Scale.

Three simple paired associates must be learned by repeated auditory presentation. In one form of the test, for example, the pairs are 'cabbage–pen', 'knife–chimney', and 'sponge–trumpet'. The examiner reads the list after telling the subject to remember the pairs that go together. The stimulus words are then given alone in random order, and repeated with appropriate corrections for errors until the subject achieves three consecutive correct responses on every one of the three different stimulus words. Any given stimulus word is dropped out as soon as its own criterion is reached. The score is the sum of the times the stimulus words must be presented before the total criterion is reached.

The test has proved to be a sensitive indicator of memory disorder in the elderly and to be independent of the patient's verbal intelligence. It is useful for measuring impairment in the acquisition phase of memory, but abnormally poor scores may be obtained in severely depressed and perplexed elderly subjects without evidence of brain damage (Post 1965). The test has been shown to correlate highly with the Modified Word Learning Test and the Synonym Learning Test (Kendrick *et al.* 1965; Bolton *et al.* 1967).

Isaacs and Walkey (1964) have prepared a simpler and shorter form that is less fatiguing and can be administered along with the clinical interview.

Three easy paired associates are given, and tested three times only in random order ('knife–fork', 'east–west', 'hand–foot'). The procedure is then repeated with three rather harder associates ('cup–plate', 'cat–milk', 'gold–lead'), and the result is simply scored in terms of the number of errors from 0 to 18. Normal scores were judged to be in the range of 0–2, moderate impairment 3–9, and severe impairment 10–18.

The range of functions covered includes attention, registration, short-term recall and, to some extent, verbal learning. Motivational factors are clearly involved as well. Goldstein *et al.* (1988) investigated paired associate learning in patients who had undergone unilateral temporal lobectomy. A verbal paired associate task differentiated between left and right lobectomies better than did a test involving paired associate learning of designs, but when used together the two tests provided optimal discrimination between the two groups of patients.

Object Learning Test

Kendrick *et al.* (1979) have described an Object Learning Test that has proved more acceptable and less stressful to elderly patients than the Synonym Learning Test. This is again used in conjunction with the Digit Copying Test for aiding the distinction between the depressed and the demented elderly. The battery can be administered in approximately 10 minutes, and its reliability and validity have been examined on large samples of patients and controls.

Four cards are divided into 25 equal sections within which there are drawings of familiar objects (e.g. a comb and a teapot). The first card

contains 10 items, the second 15, the third 20 and the fourth 25. Six of the items are repeated across all four cards and are always in the same position. Some items form a category across the cards. The cards are exposed to the subject for a standard length of time, and the score represents the total number of correct items recalled.

List learning tests

Tests examining the learning of word lists have a number of advantages. They provide information about the immediate memory span, the shape of the learning curve and the nature of the learning strategies employed (or their absence). In addition they give evidence of such matters as proactive interference and confabulation. Lezak (1995) reviews the two tests most widely used at present: the Rey Auditory Verbal Learning Test and the California Verbal Learning Test.

The *Rey Auditory Verbal Learning Test* consists of five presentations of a 15-word list, after each of which the subject must recall as many words as he can. A second 15-word list is then presented and tested for recall. The subject is then immediately asked to recall as much as he can of the first list, and retention is examined 30 minutes (or even 24 hours) later.

After each presentation the examiner writes down the words exactly as they are recalled. Scores are made of total words correctly recalled, of intrusions from one list to the other, and of errors made (i.e. words not on the lists). The shape of the learning curve over the repeated presentations of the first list can be examined, also retention after the period of delay. 'Primacy' and 'recency' effects (better recall of words towards the beginning and end of the list) are usually shown by normal subjects, but the primacy effect is often lacking when learning ability is defective. Extensive normative data are available for the test.

The *California Verbal Learning Test* is similar to the above, but includes 16 words which belong to four defined categories. This allows the subject's learning strategies to be examined more closely. Category-cued recall is tested as well as free recall, and a recognition trial is included.

Recognition memory tests

Warrington (1974, 1984) has described a simple technique for separately assessing verbal and non-verbal memory by means of an easily administered recognition memory task. A recognition paradigm is used in preference to free recall, since recognition tasks appear to be less vulnerable to anxiety and depression. Moreover, identical procedures can be followed for the verbal and non-verbal material, allowing direct comparisons between the two. It is sometimes claimed that poor performance on recognition memory tests along with only moderately impaired recall indicates feigned memory loss.

The material consists of 50 high-frequency words, each printed on a card, and 50 photographs of unknown faces. The words are presented to the subject at 3-second intervals, and he is asked to respond 'yes' or

'no' each time according to whether he judges the word to be pleasant or not pleasant. This strategy is adopted to ensure attention to the words. Recognition is tested immediately the presentation is complete by showing pairs of words, one of which is new and one of which has already been shown. A choice must be made each time between the two items.

The 50 photographs of faces are then shown at 3-second intervals, again with the requirement that the subject decides at each presentation whether the face is pleasant or unpleasant. Recognition is again tested as soon as presentation is complete by a similar forced-choice technique.

The Camden Memory Test Battery (Warrington 1996) is a shortened version of the above that probes recognition memory for words, faces and drawings. It is quick to and easy to administer but may be difficult for those patients who cannot keep up with the speed of presentation of material.

Benton Visual Retention Test

This visual recall test requires the reproduction of a series of geometrical figures shortly after their inspection (Sivan 1992).

The subject must draw the designs from memory after each card has been exposed for 10 seconds and then removed. The test can be varied by giving shorter exposures, or by imposing delays before reproduction is required. Copying of the designs while the card is in front of the subject allows separation of memory difficulties from visuo-perceptual difficulties. Performance is scored in terms of the number of designs correctly reproduced and the number of errors made. Additional qualitative information may be derived from inspection of the type of errors committed: distortions, omissions, perseverations, rotations, misplacements and errors of size. Three parallel forms of the test are available.

Performance correlates highly with intelligence and chronological age, but normative data are available to make allowance for this. The value of the test in differentiating brain-damaged and non-brain-damaged groups has been repeatedly upheld, and it has proved to be sensitive to early cognitive decline (Lezak 1995). This is probably because the test involves so many different capacities: spatial perception, visual and verbal conceptualisation, short-term retention and recall, and visuoconstructive abilities. It is sensitive to left brain damage as well as right since many of the designs can be conceptualised verbally.

Rey-Osterrieth Test

This involves the copying of a single geometrical figure of complex design, then testing reproduction from memory some time later (Rey 1941; Osterrieth 1944). The initial copying phase therefore tests for attentional neglect and praxic skills.

The figure is too complex to be adequately verbalised, hence the test is of visual non-verbal memory. The subject is first asked to copy the design as accurately as he can with the original before him. Forty minutes later and without previous warning he is asked to draw the

figure again, but this time from memory. The initial copying reflects any drawing disability or disorder of spatial perception, but the recall score reflects in addition any visual memory impairment.

The test usefully complements those which measure verbal memory functions. Patients with temporal lobe damage in the hemisphere dominant for speech tend to show little impairment with the Rey–Osterrieth Test, in contrast to their difficulties with verbal memory tests. However, right temporal lobectomy leads to a slight but significant defect on copying the figure, and a pronounced and disproportionate impairment when tested for delayed recall. Lezak (1995) reviews the extensive literature on the patterns of deficit seen with different brain lesions. Patients with parietal lobe lesions appear to show relatively stable retention despite having difficulty in copying the figure initially.

Adult Memory and Information Processing Battery

This brief battery of memory tests has British norms, stratified for age, and a parallel form is available (Coughlan & Hollows 1985). There are four memory subtests and two information-processing tests.

- Short Story Recall: recall is tested immediately after presentation and again after a 30-minute delay.
- Figure Copy and Recall: a complex two-dimensional figure is copied and recall is tested immediately and after a 30-minute delay.
- List Learning: a list of 15 words is presented in the same order for a maximum of five trials. A distracter trial is then presented, for which recall is tested, and then delayed recall of the original list is tested. The test assesses rote learning and susceptibility to interference.
- Design Learning: an abstract design must be learned, with up to five presentations. Recall of a distraction design is then followed by delayed recall of the original design. This again assesses rote learning and susceptibility to interference.
- Information Processing: tested by number cancellation and digit cancellation tasks.

Rivermead Behavioural Memory Test

This battery of tests was designed to be more ‘ecologically’ valid than most formal memory tests in that it emphasises skills needed in real-life situations (Wilson 1987; Wilson *et al.* 1991). It assesses memory impairment in terms of everyday memory functioning, thus bridging the gap between laboratory-based and naturalistic measures of memory. Four parallel forms of the test are available to allow repeat assessments during the course of rehabilitation. Good levels of correlation with standardised memory tests show that the battery is a valid indicator of memory functioning. Norms are available for adults and separately for elderly patients, and it may be adapted for use with children. A shortened form for use with aphasic patients has been shown to be sensitive to memory deficits rather than to the effects of language impairment (Cockburn *et al.* 1990). The several subtests include the following.

- 1 Orientation: tested for time and place and knowledge of the date.
- 2 Remembering a Name: the subject is told the first and second name that goes with a photograph, and recall of these is tested when the photograph is re-presented later in the session.
- 3 Picture Recognition: 10 line drawings of common objects are shown for 5 seconds each, and after a short delay the subject is asked to identify them from a set of 20.
- 4 Face Recognition: five photographs of faces seen a few minutes earlier must be identified out of a group of 10.
- 5 Story Recall: a short story similar to a newspaper item is read to the subject who is asked to repeat it immediately and again some 15 minutes later.
- 6 Route Memory: a short route around the room is demonstrated and copied immediately by the subject. Recall is required some 15 minutes later.
- 7 Prospective Memory: three innovative methods are used to test the subject’s capacity to remember to do something.
 - (a) At the start of the session an object (such as a comb or a key) is borrowed from the subject and hidden while the subject looks on; he must ask for it and remember where it was hidden at the end in response to a specific cue (e.g. ‘We have now finished this test’).
 - (b) When an alarm rings the subject must remember to ask a specific question, told to him when the alarm was set 20 minutes earlier (e.g. about the next appointment).
 - (c) He must remember an errand, e.g. to leave an envelope at a specific location along the route around the room.

Autobiographical Memory Interview

The Autobiographical Memory Interview (Kopelman *et al.* 1990) is a semi-structured interview consisting of two parts; the first assesses recall of facts from the patient’s past life while the second assesses recall of specific incidents. Each part covers three epochs: childhood, early adulthood and the recent past. Administration time is 20 minutes and comparative data from amnesia patients and healthy controls are provided. The test is useful in the range of organic conditions especially dementia but is also of value in assessing fugue states.

Frontal lobe (‘executive function’) tests

Verbal fluency tests

A large number of tests can be used for assessing the reduction in verbal fluency associated with frontal brain lesions, especially left frontal lesions. These are reviewed by Lezak (1995). The ‘FAS’ test is briefly described earlier in the chapter (see Verbal fluency) and is part of the FAB. Written tests of word fluency have been devised, also tests of ‘design fluency’ which are somewhat more affected by right frontal damage than left.

Wisconsin Card Sorting Test

This complex sorting test has proved to be particularly sensitive to frontal lobe damage (Milner 1963). It has accordingly achieved considerable importance in neuropsychological testing, since frontal lesions may sometimes be difficult to detect by other psychometric procedures.

The material consists of 64 cards, each containing from one to four geometrical figures. These consist of any one of four shapes (triangles, stars, crosses and circles) in any one of four colours. Four stimulus cards are set out before the subject who must sort the remainder beneath them. His task is to discover by trial and error whether he is required to sort according to colour, form or number, the clue being the examiner's remark of 'right' or 'wrong' after each response is made. In administering the test the subject is required to sort first of all by colour, all other responses being called wrong; then when he has achieved 10 consecutive correct responses to colour, the required sorting principle shifts without warning to form. Later it shifts to number, then back again to colour, and so on. The test thus combines the requirement for shifting frames of reference with a need for empirical discovery of categories. A total score can be obtained, also scores for perseverative and non-perseverative types of error.

Nelson (1976) has reported a simplified and improved version of the test (Modified Wisconsin Card Sorting Test) in which those cards which share more than one attribute with a stimulus card have been eliminated. Possible ambiguities for the patient are thereby reduced and the time of administration considerably shortened. The total number of cards to be sorted in the modified test is reduced from 64 to 24.

Milner (1963) obtained clear evidence that impairment was closely related to lesions of the frontal lobes of either hemisphere, with no comparable effects from lesions in other areas of the brain. The impairment was chiefly seen with lesions of the dorsolateral convexities of the frontal lobe, rather than with inferior and orbital lesions. Moreover, the errors in the patients with frontal lobe lesions were chiefly of the perseverative type. These results were obtained in patients with focal cortical excisions for epilepsy. They were broadly confirmed by Drewe (1974) in a heterogeneous group of brain-damaged patients. Certain qualitative differences were found between the nature of the errors with left and right frontal lesions, the former producing the greater overall impairment. Grafman *et al.* (1990) confirmed an excess of perseverative errors in veterans with left dorsolateral frontal and left anterior temporal lobe penetrating head injuries.

Stroop tests

A variety of tests derive from the work of John Ridley Stroop (1935) on the interference that can arise between word reading and colour naming. Lezak (1995) reviews the several formats available. All are based on the observation that it takes longer to read printed colour names when they are printed in (and/or surrounded by) coloured ink different from the name of the colour word. This may be due to a variety of factors: response conflict, failure of response inhibition, or failure of selective attention. Studies have shown that the technique is sensitive to the effects of closed head injury, and that patients with left frontal lesions perform especially badly.

Pardo *et al.* (1990) carried out PET scans during performance on the test to reveal the brain areas involved in resolu-

tion of the interference effect. An extensive distributed network of regions was shown to be involved (left premotor, left post central, left putamen, supplementary motor area, right superior temporal gyrus and bilateral peristriate cortex), but the most robust responses were observed in the anterior cingulate region.

Tests vary in the number of words and colours employed, and whether the requirement is to read out the colour names or to report the colour in which each word is printed. Scoring may be by time, number of errors made, or number of items correctly performed within a designated time period. The Stroop Neuropsychological Screening Test (Trenerry *et al.* 1989) is conducted as follows.

Columns of four colour names are presented (red, blue, green and tan), all being printed in colours incongruent with the colour name. The subject must first read the colour names aloud as quickly as possible. In the second, crucial condition there are similar columns of colour names but this time the subject must say what colour ink the word is printed in. Thus, for example, if the word 'red' is printed in blue the subject must say 'blue'. The number completed correctly in 120 seconds is compared with two age bands of norms.

Cognitive Estimates Test

Shallice and Evans (1978) noted that a patient with selective frontal lobe damage showed gross inability to produce simple cognitive estimates despite having an IQ at the same level as prior to injury. In effect the patient was unable to select the appropriate cognitive plan for answering the question and failed to check the putative answer (see Chapter 2 and Tests of frontal lobe function).

The value of the procedure was checked on groups of patients with anterior and posterior cerebral lesions, by devising a series of questions such that the appropriate plan for answering them was not immediately apparent yet required no specialist knowledge. Scoring systems for the accuracy or bizarreness of the replies were established. The frontal lesion patients performed significantly worse than the posterior group, independently of the hemisphere involved. This persisted on partialling out scores on Raven's Matrices, indicating that the differences were not simply due to defects of reasoning or general intelligence. Examples of the questions used in the test are as follows.

- How tall is the average English woman?
- What is the best paid job in Britain today?
- What is the largest object normally found in a house?
- How fast do racehorses gallop?
- What is the height of the Post Office Tower?
- What is the age of the oldest person in Britain today?
- What is the length of an average man's spine?

Strategy application tests

Some patients with known frontal damage can be observed to perform surprisingly well on tests of frontal lobe function yet show marked organisational difficulties in everyday life.

Shallice and Burgess (1991) suggested that this might be due to the constraints incorporated in clinic-based tests where the subject has an explicit problem to be tackled, usually under guidance from the examiner. In most routine tests the patient rarely needs to organise and plan his behaviour over substantial periods of time, set a range of goals or deal with interleaving priorities. Yet 'executive' abilities of this nature are required in everyday activities.

Behavioural Assessment of Dysexecutive Syndrome

The Behavioural Assessment of Dysexecutive Syndrome (Wilson *et al.* 1996) contains a number of such tests designed to have high 'ecological' validity and has been standardised in control subjects aged between 16 and 87 years. It has six subtests and a 20-item questionnaire known as the Dysexecutive Questionnaire, which is completed by the patient and a professional or informal carer. This assesses subjective awareness of cognitive problems such as abstract thinking problems, impulsivity, apathy, distractibility and unconcern for social rules, scored on a 5-point scale from 0 (never) to 4 (very often). The two versions enable a discrepancy score to be calculated: people with early Alzheimer's disease and traumatic brain injury frequently underestimate their problems in comparison to their carer. The other subtests include the following.

- Rule Shift: subjects first learn to respond 'yes' to a red card and 'no' to a black card. Subsequently, the rule changes and the subject has to respond 'yes' if the current card is the same as the previous one: red cards may not necessarily require a yes response.
- Action Program: this is a puzzle involving a number of objects (a beaker, a cork, some water, a tube, a hook, etc.). Abiding by certain rules, the subject has to get the cork out of the tube by floating the cork on the water and then emptying the water through the tube. The task requires novel problem solving and physical manipulation skills.
- Key Search: a square on a piece of paper stands for a field in which the subject has lost his keys. Starting from a point outside the field, the subject draws a line representing the route he would take to find his keys. A systematic search strategy which covers the area without doubling back scores the most marks.
- Temporal Judgement: this comprises four questions such as 'How long does it take to blow up a party balloon?' and 'How long do most dogs live for?' A sensible guess is required, rather like the Cognitive Estimates Test.
- Zoo Map Test: this requires the patient to plan a route to visit six of twelve locations in a zoo, according to rules regarding the starting and finishing points, and using designated paths. In one scenario a planned route to follow is provided, while in another the patient has to plan a route, which requires forethought.
- Modified Six Elements: this requires the subject to carry out a group of six open-ended tasks in a fixed period of time (10 minutes) so as to maximise the overall score obtained. The tasks are divided into two sets of three: dictating details of a route to and from the hospital, carrying out arithmetical problems of increasing difficulty, and writing down the names of pictures of objects. Detailed written instructions are presented concerning rules to be followed in carrying out the tasks. Basically, the test involves devising a simple plan, scheduling the tasks

efficiently (not flitting from one to another), and keeping a check on time (a clock is placed in front of the subject).

Multiple Errands Test

The Multiple Errands Test is more complex, requiring the subject to complete a number of tasks away from the hospital in an unfamiliar shopping precinct. Thus it involves the dovetailing of multiple activities in a real-life situation where minor unforeseen events can occur. Again detailed 'rules' must be followed and the subject's behaviour is observed throughout.

The tasks principally involve buying specified items, but one requires more ingenuity and social judgement, namely to write on a card the name of the shop likely to contain the most expensive item on sale in the precinct, the price of a pound of tomatoes, the name of the coldest place in Britain and the rate of exchange of the French franc on the previous day. Thus a range of goals must be defined, actions planned, outcomes evaluated and appropriate adaptations made. Scores are made in terms of efficiency, rule breaks, misinterpretations and task failures. Qualitative aspects of performance are also charted. Goldstein *et al.* (1993) have reported impaired performance on the Multiple Errands Test in a patient with a circumscribed excision on the left frontal lobe, who showed preserved intelligence and memory and normal performance on other tests of frontal lobe function. The planning difficulties elicited by the test mirrored those that the patient experienced in everyday life.

Hayling Test

Patients complete 30 sentences, read by the examiner, from which the last word is omitted. In the first 15 sentences, the subject completes the sentence with a word that makes sense: 'The captain wanted to stay with the sinking . . . ship'. In the second set of sentences, the subject must come up with a final word that does not make sense in the sentence: 'London is a very busy . . . ice-cream'. Response latency is the main measure and the difference between the first and second phases of the test is an indicator of response suppression time.

Brixton Test

This measures the ability to detect rules in sequences of non-verbal stimuli. It usually takes between 5 and 10 minutes to perform. Errors are scored and converted to a scaled score of between 1 and 10. The subject is shown 10 circles on a page, one of which is filled. The object is to predict where the next filled circle will be after a short sequence (Burgess & Shallice 1997).

Tower of London Test

Shallice (1982) introduced this test, derived from the Tower of Hanoi oriental puzzle.

The subject must move a number of coloured beads placed on three upright poles so as to reproduce a pattern set by the examiner. It is a test of planning, in that the subject must look ahead and divide the task into a series of subtasks, and carry these out in the correct sequence in order to obtain the desired solution. Different grades of difficulty can be presented in terms of the minimum number of moves allowed to reproduce the pattern.

Shallice (1982) found that patients with left frontal lesions performed significantly worse than patients with brain lesions in other locations.

Trail Making Test

The Trail Making Test consists of 25 circles distributed over a sheet of paper. In the first part the circles are numbered, and the subject must draw a line connecting them in numerical sequence as quickly as possible. In the second part the circles contain both numbers and letters and the subject must alternate between numbers and letters as he proceeds in ascending sequence. The score is the time taken over the task. Errors must be corrected and are thus incorporated in the time scores.

Performance on the test requires spatial analysis, motor control, alertness, concentration and ability to shift attention between alternatives. In consequence, it is likely to be affected by brain damage in many locations. When the subject takes disproportionately longer to complete the second part than the first ('Trail B'), there are likely to be difficulties with complex conceptual tracking or with flexibly changing sets during ongoing activity. For this reason the test is sometimes employed when frontal damage is suspected. Impulsive errors may be noted, and perseverations revealed.

More generally, Reitan (1958) demonstrated excellent differentiation between brain-damaged and non-brain-damaged subjects, and this has since been repeatedly confirmed. However, both age and education have significant effects on performance, and depression has been shown to interact with the slowing produced by ageing (Lezak 1995).

Goldstein–Sheerer tests

Tests developed by Goldstein and Sheerer (1941) were formerly extensively employed for investigating capacity for abstract thinking and categorisation, but are now little used. Various tests in the group explore ability to abstract common properties of objects, to break up a whole into parts, and to shift from one frame of reference to another. Accordingly they can be particularly vulnerable to frontal lobe lesions.

This type of test relies heavily on qualitative observations, being concerned with the methods employed by the subject as well as with the end-point achieved, and it is difficult to obtain objective methods of scoring.

The Goldstein–Sheerer Cube Test consists of cubes with sides of different colours, which must be assembled to match printed designs. The Gelb–Goldstein Colour Sorting Test consists of woollen skeins of different colours and shades which must be selected by colour or brightness to go with chosen samples. The Gelb–Goldstein–Weigl–Sheerer

Object Sorting Test consists of a miscellaneous group of objects that must be sorted into designated groups (according to form, colour, use, etc.). The Colour Form Sorting Test utilises circles, squares and triangles in different colours that must be sorted according to one common property and then another. The Goldstein–Sheerer Stick Test requires the subject to copy geometrical designs with a number of sticks of different lengths.

Vigilance tests

A number of tests aim to measure the subject's capacity for the continuous monitoring of stimuli over relatively long periods of time. Such 'vigilance' tests come closer than most other procedures to measuring ability for sustained attention and concentration. They have been shown to be sensitive to brain damage, and can have special advantages for detecting minor degrees of clouding of consciousness.

In routine clinical practice the simple procedures outlined in Chapter 1 will often suffice for obtaining an estimate of sustained attention. More complex information processing tests, such as the Paced Auditory Serial Addition Test (PASAT), in which digits are presented auditorily at two speeds, may be employed in patients who can cooperate with the procedure.

A further series of tests requires the subject to react rapidly in response to signals that arrive in a preset random manner. Efficient performance requires the prolonged maintenance of a high level of attention, and rapid activation of perceptual and motor mechanisms. Their disadvantage is that special apparatus is required.

The simple estimation of reaction times has often shown good differentiation between brain-damaged subjects and controls (Blackburn & Benton 1955; Benton & Joynt 1959). De Renzi and Faglioni (1965) showed that measures of the reaction time to visual stimuli were more efficient than Raven's Matrices in discriminating between normal subjects and patients with focal cerebral lesions. However, Benton *et al.* (1959) found that reaction times were also significantly slowed in schizophrenic patients.

Rosvold *et al.* (1956) explored the value of a Continuous Performance Test in which letters were exposed by a revolving drum at 1-second intervals for periods of up to 10 minutes. The subject was required to press a button whenever the letter 'X' appeared, or in a more difficult version whenever an 'X' was preceded by an 'A'. Brain-damaged adults and children were shown to be significantly poorer at the test than normal controls. Other versions exist in which the repetition of a letter is the target. This may be sequential ('1-back') or separated by one or more intervening letters ('*n*-back'), which tests working memory.

Halstead–Reitan Battery

This extensive battery represents one of the most ambitious attempts to produce a comprehensive test for the investigation of brain damage. Reitan (1966) and Russell *et al.* (1970) describe its evolution and the attempts made to explore its

diagnostic usefulness. The aim has been not only to detect brain damage but also to indicate whether this is likely to be focal or diffuse, lateralised to the right or left hemisphere, and whether acute and progressive or relatively static. Individual components of the battery are frequently used alone. Some of the principal tests involved are as follows.

- Halstead's Category Test consists of groups of pictures displayed on a screen, in response to which the subject must press one of four levers. The lever required at each exposure is determined by certain unifying concepts among the group of pictures, and the subject must discover the rules by repeated trial and error. It is thus a relatively complex concept formation test that requires the subject to note similarities and differences, to set up hypotheses and to test and modify them.
- The Critical Flicker Frequency Test measures the speed of flicker required before repeated brief exposures of light become fused.
- The Tactual Performance Test requires the subject to fit blocks into their spaces on a board while blindfolded and later to draw the board from memory. It requires tactile form discrimination, manual dexterity and coordination, and the visualisation of spatial configurations.
- The Rhythm Test requires the subject to differentiate between several pairs of rhythmic beats, and assesses alertness, ability for sustained attention and ability to perceive differing rhythmic sequences.
- The Speech Sounds Perception Test consists of a series of tape-recorded nonsense words that the subject must identify by selection from printed alternatives.
- The Finger Tapping Test is a simple measure of motor speed.
- The Time Sense Test requires the subject to observe the time taken for a hand to rotate around a dial, then after several practice trials to estimate the time from memory.
- The Halstead-Wepman Aphasia Screening Test contains items for testing ability to name objects, spell, identify single numbers and letters, read, write, calculate, name body parts and distinguish right from left.
- The Trail Making Test (described earlier) is added as a further part of the battery.
- Other tests include detailed assessments of the accuracy of sensory perception on each side of the body, and tests of finger recognition, graphaesthesia and stereognosis.

Computerised psychological tests

Tests that can be administered by computer have an obvious attraction for certain purposes, either to economise with the time of a psychologist when large numbers of patients need to be examined in research, or to allow very detailed exploration of specific psychological functions. In both contexts they have special advantages in permitting accurate recording of response times in addition to examining levels of performance.

Cambridge Neuropsychological Test Automated Battery (CANTAB)

An ingenious and sensitive group of automated tests was developed in the context of exploring deficits in patients with Alzheimer's dementia and Parkinson's disease (Morris

et al. 1987; Fray *et al.* 1996; Robbins *et al.* 1998; Robbins & Sahakian 2002). A laptop computer fitted with a touch-sensitive screen is used to record the patient's responses and reaction times. Component tests include the following, some of which are based on paradigms derived from animal work. The battery is used most in research contexts and also to evaluate new treatments. Since its introduction, it has frequently been updated and expanded. The original was rather limited in the coverage of human psychological functions (e.g. language and semantic memory).

Visual memory tests

Delayed match to sample (DMTS) assesses forced choice recognition memory for novel non-verbalisable patterns. This tests both simultaneous and short-term visual memory. Paired associate learning is a stringent test for episodic memory and associative learning. Pattern and spatial recognition memory are also part of the battery.

Executive function, working memory and planning

Intra/extra-dimensional (IED) shift task tests rule acquisition and attentional set shifting. This is a computerised analogue of the Wisconsin Card Sorting Test, and is sensitive to cognitive changes associated with schizophrenia, Parkinson's disease, and dopaminergic-dependent processes. The Stockings of Cambridge (SOC) is a version of the Tower of London Test and assesses spatial planning and motor control and is claimed to probe the dorsolateral prefrontal cortex. There are also spatial span (a visuospatial analogue of the Digit Span Test) and spatial working memory tests.

Attention tests

These tests measure different aspects of attention and reaction time. They include the simple and choice reaction time tasks with different response modes and increasing complexity.

- Match to Sample Visual Search (MTS) is a simultaneous visual search task with response latency dissociated from movement time. Efficient performance on this task requires the ability to search among the targets and ignore the distractor patterns that have elements in common with the target. This test may help to differentiate between primary movement disorders and dementing conditions.
- Rapid Visual Information Processing (RVP) is a test of sustained attention (similar to the Continuous Performance Task where a sequence of numbers has to be detected within a continuous stream).

Emotional decision-making tests

- Affective Go/No-go (AGN): this is a lexical decision test on words whose valence (positive and negative) is manipulated. Different reaction times to the word types is used in the analysis.
- Cambridge Gambling Task (CGT): this test has the appearance of a simple betting game. It requires the evaluation of risk and the ability to defer gratification. The likely neural substrate for this task is thought to be the orbitofrontal prefrontal cortex.

Semantic/verbal memory tests

These tests, which address semantic and/or verbal memory, are relatively new additions to the CANTAB battery. They include computerised versions of standard tests such as graded naming and verbal recognition memory.

Dementia questionnaires and rating scales

A number of questionnaires are available for making an approximate assessment of functions that tend to be impaired in dementing illnesses. These are not psychometric tests in the ordinary sense, but questionnaires filled in by doctors, nurses or relatives who have observed the patient closely. They often include questions relevant to social and emotional functioning in addition to observations about the patient's cognitive status.

Standardisation is often incomplete, but the questionnaires can give useful information in certain settings. Some have especial value in quantifying the degree of impairment when patients are too severely incapacitated to yield scores on formal psychometric tests. Others are useful for research purposes in allowing the separation of groups according to overall severity of disability. In clinical practice they can serve as an approximate screening device, or they can be repeated after an interval of time to gauge the rate of decline or improvement. Morris *et al.* (2000) discuss the principles behind psychometric assessment in the elderly and give some useful clinical pointers.

Blessed's Dementia Scale

Blessed *et al.* (1968) used a standard dementia scale in their study of the relationship between impairments of function and severity of neuropathological changes in the brains of old people.

The questionnaire is administered to a close relative or friend, who must answer the questions on the basis of the patient's level of performance during the preceding 6 months. One group of questions contains items concerning competence in personal, domestic and social activities, such as ability to perform household tasks, to cope with small sums of money, to find the way in familiar surroundings and to recall recent outings and visits. The next group concerns changes of habits, such as impairment of eating, dressing and sphincter control. The third is relevant to change in personality, interest and drive, such as increased rigidity, egocentricity, coarsening of affect, impaired emotional control or the abandonment of habitual interests.

Middlesex Elderly Assessment of Mental State (MEAMS)

This measures orientation and core neuropsychological functions in all 12 subtests covering perception, memory, language and executive functions. Each subtest is scored and a cut-off score determines pass or fail. The total number of subtests passed gives the global performance and outcome is classified into three ranges: impaired (0–7), borderline (8–9) and normal (10–12). It has reasonable validity and reliability (Golding 1989; Yaretzky *et al.* 2000) and can distinguish dementia from depression in most cases. However, it perhaps lacks sensitivity since it is predicated on the claim that all items should be passed by a 'normal' individual regard-

less of intellect, in both dementia and stroke (Cartoni & Lincoln 2005).

Geriatric Mental State Schedule

The Geriatric Mental State Schedule (GMS) is not simply a questionnaire but a standardised, semistructured interview for examining and recording the patient's mental state. It takes 30–40 minutes to administer and covers the period of a month prior to examination (Copeland *et al.* 1976). The GMS allows classification of elderly patients by symptom profile and can demonstrate changes in the profile over time. Good reliability between raters has been shown both for individual items and for diagnoses made on the basis of the schedule (Copeland *et al.* 1976). In a correlational procedure 21 factors were produced, including three dealing with cognitive impairment ('impaired memory', 'cortical dysfunction' and 'disorientation') and others concerned with depression, anxiety, somatic concerns, etc. The ability of these factors to discriminate between organic and non-organic disorders of the elderly has been demonstrated (Gurland *et al.* 1976).

The related Comprehensive Assessment and Referral Evaluation Schedule (CARE) (Gurland *et al.* 1977) contains psychiatric components largely derived from the GMS, along with questions covering medical disorders, social functioning and capacity to undertake activities of daily living. Henderson *et al.* (1983) have combined parts of both instruments to produce an interview for use in community surveys.

Further developments with the GMS have involved computerisation of the data to yield diagnostic information (Copeland *et al.* 1986). The system, known as AGE CAT, summarises symptom components and arrives at levels of confidence with which diagnoses of organic brain syndrome, schizophrenia, depression, for example, can be made. GMS-AGE CAT diagnoses of dementia and depression have been shown to agree well with diagnoses made according to DSM-III criteria (Copeland *et al.* 1990). The addition of data from an informant interview (the History and Aetiology Schedule, HAS) allows further refinement and subdivision of diagnoses (HAS-AGE CAT), including subdivision of dementia into senile dementia of the Alzheimer type, multi-infarct dementia and alcohol-related dementia. HAS-AGE CAT is being used in ongoing studies of the prevalence and incidence of dementia in the elderly (Copeland *et al.* 1992).

Cambridge Examination for Mental Disorders of the Elderly (CAMDEX)

Published in 1988, this test has become widely influential (Roth *et al.* 1988) and has been updated and revised. It incorporates within a single standardised instrument all components needed to identify dementia in the elderly, even in the early stages. This is graded according to severity and subdivided into its main subcategories (senile dementia of Alzheimer type, vascular dementia, mixed forms, and dementia secondary to other causes). Items relevant to other

confounding diagnoses are also included: delirium, depression, paranoid or paraphrenic illness, and anxiety and phobic disorders.

The schedule begins with a structured patient interview, incorporating questions about the present mental state, the previous personal and medical history, and the family history. A standardised assessment is made of a broad range of cognitive functions, also of other aspects of the mental state, appearance and demeanour. A brief physical and neurological examination is recorded along with the results of investigations. Finally, observations and information from a relative or other informant are systematically recorded. Administration involves approximately 60 minutes with the patient and a further 20 minutes with the informant. The items of information obtained from these multiple approaches are then assembled to produce diagnostic categories according to operational diagnostic criteria.

The subsection dealing with the cognitive examination (the CAMCOG; revised edition published in 1999) is particularly useful, being specially engineered to be 'user friendly' for non-psychologists. It incorporates tests of orientation, memory, language, perceptual abilities, praxis, attention and abstract thinking and is scored out of 107, with 80 used as a cut-off for dementia. Items contained within it comprise the MMSE (see Mini-Mental State Examination, earlier in chapter) but the CAMCOG is more thorough in its assessment. It can stand alone for certain purposes as a valuable brief means of performing a neuropsychological examination.

The Consortium to Establish a Registry for Alzheimer's Disease has a neuropsychology battery that includes verbal fluency, naming, word list learning, word list recall, word list recognition, constructional praxis as well as the MMSE. This is available worldwide in many translations and appears to be useful as a screening test for dementia.

Aptitude tests

Vineland Social Maturity Scale

The Vineland Social Maturity Scale (Doll 1947) has been mainly used for studies in child development and mental retardation, but can also be useful in providing a measure of social functioning in brain-damaged adults. Repeat administration after an interval of time can reveal gains or losses in the social field, usefully supplementing measures of intellectual ability.

The scale consists of 117 items that sample various aspects of social ability: capacity for self-care, social independence in personal activities and social responsibility. The items are scored by interviewing someone closely acquainted with the patient. The chief categories of function measured by the scale are as follows.

- Self help general: for example 'cares for self at toilet', 'tells time to quarter hour'.

- Self help eating: for example 'drinks from cup or glass unaided', 'uses table knife for spreading'.
- Self help dressing: 'dresses self except for tying', 'bathes self assisted', 'bathes self unaided'.
- Self direction: 'makes minor purchases', 'uses money providently'.
- Occupation: 'uses tools or utensils', 'does simple creative work'.
- Communication: 'prints simple words', 'makes telephone calls', 'follows current events'.
- Locomotion: 'goes about neighbourhood unattended', 'goes about home freely', 'goes to distant places alone'.
- Socialisation: 'plays simple table games', 'assumes responsibilities beyond own needs', 'shares community responsibility'.

Specific disorders

Head Injury

Simon Fleminger

Maudsley Hospital, London

The size of the problem presented by head injuries to medical services and to the economy generally is immense. About 200 per 100 000 population per year suffer a head injury (Bruns & Hauser 2003). In the majority of these the head injury is classified as mild (Sorenson & Kraus 1991), yet perhaps as many as 100 per 100 000 per year go on to suffer significant disability at 1 year (Thornhill *et al.* 2000). Many of these people are young and will suffer long-term disability. As noted by Headway, the UK national head injury association, a 'head injury is for life'. In 1991 the economic cost in the USA was put at more than \$48 billion per year (Krauss & Chu 2005). However, in the developed world, head injuries may be declining, probably reflecting better road safety, at least in part. Thus in the USA over the period 1980–1995 there was a 50% reduction in hospitalisation for head injury (Thurman & Guerrero 1999). The outlook in the developing world may be less encouraging. High levels of two-wheeled vehicle use, rapidly increasing car ownership but poorly developed road safety infrastructure, and lack of ambulances mean that disability due to head injury is on the increase (Gururaj 2002). The vast majority of head injuries in civilian life are closed injuries and result from acceleration/deceleration forces. When the term 'head injury' is used in this chapter it will by and large refer to closed head injury. Risk factors for sustaining a traumatic brain injury (TBI), synonymous with head injury, include male sex, younger age (peak at 15–24 years with a smaller peak in the elderly), alcohol, lower socioeconomic status and a psychiatric history (Fann *et al.* 2004).

Early mortality has been considerably improved as a result of advances in the management of the early acute stages. However, the chronic sequelae remain as a serious challenge to medical care and communal resources, and this can only be reflected very approximately in statistics. Quite apart from the physical sequelae, the psychiatric consequences and their social repercussions may be judged to be signifi-

cant in upwards of one-quarter of patients who survive. Precise figures are hard to obtain because it is clear that many patients, even with severe incapacities, do not present themselves for continuing medical attention. What is virtually certain is that the mental sequelae outstrip the physical as a cause of difficulty with rehabilitation, hardship at work and social incapacity generally, and in terms of the strain thrown on the families to whom the head-injured patient returns (Thomsen 1984).

Fahy *et al.*'s (1967) follow-up of a small group of very severe civilian head injuries vividly illustrates the amount of disturbance enduring 6 years later. Only 5 of 22 patients were free from psychiatric sequelae, and psychiatric disturbance was a prominent cause of incapacity for work. Problems in the home included affective outbursts, chronic irritability, epileptiform and hallucinatory episodes and paranoid developments, in addition to impairment of intellectual processes. Yet only two of the patients had been referred for psychiatric advice during the follow-up period. It appears therefore that the psychiatrist sees only a small proportion of the problem (Deb *et al.* 1999a).

The acute phases of care following a head injury are primarily the province of the casualty officer, neurologist or neurosurgeon. Rehabilitation teams composed of therapists, with medical input usually from a rehabilitation physician or neurologist, manage the sequelae. However, neuropsychologists and psychiatrists are increasingly taking a central role in the rehabilitation phase, helping to ensure that the important long-term neuropsychiatric sequelae are properly managed. The greater part of this chapter is devoted to the long-term mental sequelae of head injury. Nevertheless, correct evaluation of the mechanisms which underlie the longer-term disturbances needs to be based on a proper understanding of the acute effects of head injury.

Pathology and pathophysiology

Biomechanics of concussion and traumatic brain injury

Concussion may be defined as an immediate and transient alteration or loss of consciousness, or other disturbance of neurological function, when sudden mechanical forces are applied to the head. Using video analysis of concussions in football players (Pellman *et al.* 2003) and data from accelerometers placed in their helmets (Duma *et al.* 2005), it has been possible to estimate the acceleration/deceleration of the head during concussive head injuries as of the order of 80–100 g over 15 ms.

Loss of consciousness is particularly likely to follow acceleration/deceleration injuries where there is a rotational component. Rotations round a coronal axis, i.e. with the head moving from side to side, are probably more likely to produce loss of consciousness than rotation around the sagittal axis as in a nodding movement of the head (Smith & Meaney 2000). This may explain why impacts to the temporoparietal area are most likely to produce concussion (McIntosh *et al.* 2000). Presumably rotational forces are particularly likely to produce the swirling movement of the brain that has been observed in monkeys after acceleration injury (Pudenz & Shelden 1946). Side impacts in car accidents are possibly more likely to be associated with severe head injury, perhaps because of the side-to-side forces as the head hits the pillar between the front and rear doors (Nirula *et al.* 2003). It was suggested that if the force is applied to the face, causing facial fractures, this acts as a buffer reducing the brain injury (Löken 1959). However, a more recent study suggests this is not the case and that, in those presenting to accident and emergency departments, a facial fracture increases the likelihood of brain injury (Keenan *et al.* 1999).

Static crush closed head injuries, in which there is no acceleration/deceleration of the brain, are relatively unlikely to produce loss of consciousness (Russell & Schiller 1949). This was confirmed in a series of bitemporal crush injuries (Gonzalez Tortosa *et al.* 2004); less than half had loss of consciousness whereas all had basal skull fractures, pneumocephalus and otorrhagia. The majority also had injury to cranial nerves VI and VII and diabetes insipidus.

In open head injuries the dura is breached and laceration of brain tissue is present at the site of impact but contrecoup is slight or even absent. The extent of the damage in open head injuries depends on the velocity of the object. Penetrating injury from a knife or spike causes localised damage around the track. Shrapnel injuries tend to be quite low velocity, producing localised damage. However, bullet wounds, particularly from modern high-velocity rifles, produce massive shock waves throughout the brain causing widespread damage and usually death.

Pathology of head injury

The more severe injuries that come to post-mortem examination show a variety of pathological changes. Some are the result of direct physical damage to the brain parenchyma, and some the result of complicating factors such as vascular disturbances, cerebral oedema and anoxia. In penetrating injuries infection may be superadded.

Contusions

Severe contusions comprise a mixture of haemorrhage and necrosis, typically near the surface of the brain, due to severe localised forces. In an individual injury, determining where the head was hit, and the direction of the forces, is often difficult. For example, in a road traffic accident there may be more than one blow to the head in quick succession. Thus the concept of contrecoup injury, with contusions occurring on the side opposite the injury, is often not a reliable predictor of contusion location. What is more telling is that there are certain sites of predilection: the orbital surface of the frontal lobes, particularly medially, and the underside and tips of the temporal lobe (Fig. 4.1). Presumably these are the sites where the brain is most at risk of being traumatised by the hard skull. When the head is at rest at the time of injury, as in assault, the lesion will be maximal at the site of impact, but when in motion, as in falls or traffic accidents, the contrecoup effect is likely to be most pronounced (Bloomquist & Courville 1947; Löken 1959).

Diffuse axonal injury

As already described, acceleration/deceleration injuries produce swirling movements throughout the brain. The resulting rotational and linear stresses tear and damage nerve fibres throughout the brain. The diffuse interruption and degeneration of nerve fibres, with breakdown and resorption of myelin and the formation of retraction balls, is called diffuse axonal injury. First reported in patients dying after very severe brain injuries, it is likely that similar changes occur in some patients with mild closed injuries as well (Strich 1956, 1969; Teasdale & Mendelow 1984). The changes are mainly confined to the parasagittal central white matter and the grey–white matter interface of the hemispheres (Fig. 4.2), the corpus callosum, and the long tracts in the brainstem. With more severe injuries small haemorrhages are seen, particularly in the corpus callosum and the parasagittal white matter.

In the longer term, severe diffuse axonal injury produces ventriculomegaly with thinning of the corpus callosum, often in the absence of sulcal enlargement. Clinically, it may present with prolonged loss of consciousness in the absence of intracerebral contusions, and later result in neurological sequelae related to damage to white matter tracts in the brainstem, particularly the superior cerebellar peduncle, with for example slurring of speech and ataxia. Diffuse axonal injury is now sometimes used to describe a clinical

Fig. 4.1 Contusions after closed head injury: composite from 50 post-mortem cases. (From Courville 1937 with permission.)

Fig. 4.2 Diffuse axonal injury shown as high signal in white matter on MRI T2 image several months after a closed head injury with about 30 minutes loss of consciousness. Posteriorly, the white matter appears normal, dark grey on T2. Anteriorly, there is high signal in the white matter. Note the flame-shaped appearance, partly because the highest signal tends to be near the white–grey matter interface, as is typical of diffuse axonal injury.

syndrome of diffuse injury where loss of consciousness is not explained by focal lesions. For example, Katz and Alexander (1994) defined patients with diffuse axonal injury as those with (i) acceleration/deceleration injury, (ii) immediate loss of consciousness and (iii) computed tomography (CT) and magnetic resonance imaging (MRI) findings of petechial white matter haemorrhages, isolated intraventricular or subarachnoid haemorrhage, diffuse swelling or normal scan. However, the use of what is essentially a neuropathological term to define a clinical syndrome in the absence of histological confirmation needs to be treated with a little circumspection.

Other sequelae

Vascular lesions

Vascular lesions include scattered punctate haemorrhages throughout the brain, along with large and small infarcts. Sometimes the whole or part of the territory of a major cerebral artery may become necrotic. Such vascular lesions probably result from a combination of factors: reduced cerebral blood flow immediately after the injury, hypotension, embolism, pre-existing atheroma, rise of intracranial pressure sufficient to occlude the arteries, and spasm of vessels due to mechanical strain at the junction of brain and vessel (Strich 1969; Graham & Adams 1971). Posterior cerebral artery strokes occur when tentorial herniation, due to brain swelling, compresses the artery (Fig. 4.3). Dissection of the major cerebral arteries, both carotid and vertebrobasilar, is a recognised complication; for example unexpected subintimal dissection of the middle cerebral artery was found in three cases with massive cerebral infarction (Rutherford *et al.* 1996).

Fig. 4.3 Posterior cerebral artery infarct following head injury. (a) T1-weighted and (b) T2-weighted MRI brain scans of a woman in her fifties several months after a severe head injury with several days' coma. On recovery of consciousness she was blind. She initially denied any problems with her eyesight, but gradually acknowledged that she was unable to see. However, she developed the persistent delusion, which lasted several years, that her eyesight would recover fully if she kept to a special high-protein diet. She would become very angry and querulous if the diet that she demanded was not offered. She required long-term residential care, partly because of moderate cognitive impairment, but also because she always refused to accept any rehabilitation or aids to help her cope with her blindness.

Patients, particularly children (Kieslich *et al.* 2002), are therefore at risk of stroke in the days following injury.

Extensive bleeding may occur into the subarachnoid space, with the appearance of blood in the cerebrospinal fluid (CSF). Subdural haematomas may collect and become organised over the cerebral hemispheres. Blood collecting in the basal cisterns or over the surface of the brain may later lead to organised adhesions that obstruct the flow of CSF and lead to hydrocephalus. Bleeding into the brain tissue itself may result in an intracerebral haematoma.

Cerebral oedema

Cerebral oedema may develop in the acute stages and further complicate the picture. It is especially liable to occur in the region of contusions, lacerations, infarcts and haematomas. Cellular mechanisms, rather than breakdown of the blood–brain barrier, may be predominantly responsible (Marmarou *et al.* 2000). Diffuse cerebral swelling is more common in children (Kazan *et al.* 1997). The raised intracranial pressure that results can have serious consequences in terms of herniation of brain tissue through the tentorium and under the falx cerebri. If severe, such ‘coning’ may be fatal. Less severe cases can be followed by focal necrosis and haemorrhage in the medial temporal lobe structures and brainstem around the aqueduct and fourth ventricle (Duret’s haemorrhages).

Cerebral anoxia

Cerebral anoxia is a common consequence of head injury. The anoxia will derive not only from cerebral oedema and other local changes, but also from hypotension, blood loss, disturbances in regulation of the cerebral circulation, and ventilatory insufficiency in the acute stages. In the ‘golden

hour’ after injury, maintenance of arterial oxygenation and blood pressure are crucial to management. Neuronal damage from anoxia will be aggravated by increased metabolic demand and accounts for various pathological findings, such as cortical necrosis in the depths of the cortical sulci, lesions in Ammon’s horn and the basal ganglia, and the disappearance of Purkinje cells from the cerebellum. Cases studied early after injury show widespread chromatolysis in neurones both in the brainstem and throughout the cortex. The importance of early metabolic and neurochemical derangements in leading to brain damage is also increasingly recognised (see below).

In children after non-accidental brain injury it has been proposed that in many the brain injury is due to global hypoxia as a result of apnoea following damage to the craniocervical junction (Geddes *et al.* 2001); relatively few children dying from ‘shaken baby’ syndrome showed evidence of diffuse axonal injury, whereas the most common finding was global hypoxic damage.

Open head injuries

In open head injuries the skull and dural coverings are perforated. Extensive local laceration may lead to large cystic cavities and ventricular dilatations. Haemorrhage may occur locally, and infection is an ever-present risk. Small fractures in the neighbourhood of the nasal sinuses may pave the way for meningitis or local abscess formation. Following gunshot wounds, cerebral artery spasm (associated with subarachnoid bleeding) may be seen (Kordestani *et al.* 1997). The fibroglial scar that follows open head injury and which may produce distortion and traction on the brain may explain the high risk of late epilepsy.

Pathophysiology: biochemical and physiological changes

Though they share much in common, particularly in the case of more severe injury, it is useful to consider on the one hand the processes that result in loss of consciousness and on the other those which result in cell damage (Nortje & Menon 2004). In the latter, it may be valuable to distinguish between the mechanisms involved in diffuse axonal injury (white matter) and those causing neuronal cell death (grey matter). These issues are reviewed in Povlishock and Katz (2005).

Loss of consciousness and coma

The pathophysiology of loss of consciousness is poorly understood, particularly for milder head injuries (McCrory *et al.* 2001). The cardinal symptoms of concussion point to a major involvement of brainstem centres. In addition to loss of consciousness there is respiratory arrest, generalised vasoconstriction, loss of corneal reflexes and paralysis of deglutition. Concussive convulsions, i.e. non-epileptic seizures immediately following the impact (McCrory *et al.* 1997), may arise in the brainstem, supporting the argument for brainstem involvement. Experimental concussion in monkeys produces surprisingly little effect on cortical electroencephalographic (EEG) rhythms and far more disturbance in the medial reticular formation (Ward 1966). Studies suggesting that cholinergic systems may be involved (Hayes *et al.* 1989) perhaps point to brainstem structures. On the other hand, it has been proposed that the forces and resulting injury usually spread centripetally, from the cortex to the brainstem (Ommaya & Gennarelli 1974), in which case only more severe head injuries affect the brainstem. However, it is probable that this hypothesis best explains the consequences of head injury that result in permanent physical damage to the brain, which may be rather different from effects that produce transient unconsciousness at milder levels of injury. Others have argued that mechanically induced cellular depolarisation, perhaps localised to the brainstem or a more diffuse cortical effect, is critical. One plausible mechanism, perhaps of greater relevance to injury resulting in coma of more than a few minutes, is that the trauma results in massive and rapid release of potassium into the extracellular space (Maroon *et al.* 2000). This is associated with excessive glutamate release and produces depolarisation of neurones and unconsciousness. This is then followed by a hypermetabolic state as Na^+/K^+ pumps are activated to restore extracellular potassium levels to normal.

Histological studies can provide only indirect evidence of the mechanism of loss of consciousness, especially since mild concussion may represent loss of function without structural alteration. Neuronal changes have been shown in the brainstem of animals in proportion to the strength of the blows inflicted (Windle & Groat 1944; Groat & Simmons 1950), but these may be secondary to cervical cord damage occasioned

by bending and stretching of the neck (Friede 1961). The MRI evidence discussed under Neuroimaging and head injury (later in chapter) suggests that hemisphere damage may be associated with loss of consciousness, with brainstem mechanisms suffering secondarily. However, prolonged coma and death is associated with pathology in the upper brainstem (Jellinger & Seitelberger 1969; Firsching *et al.* 2002; Wedekind *et al.* 2002) and thalamus (Maxwell *et al.* 2004), and with severe diffuse axonal injury (Jennett *et al.* 2001). Unsurprisingly, raised intracranial pressure early after injury predicts poor prognosis (Signorini *et al.* 1999a) and is likely to be one factor contributing to coma.

Diffuse axonal injury

Experimental models of injury have indicated that the changes of diffuse axonal injury take hours to develop (Povlishock & Coburn 1989). At the moment of impact there is little evidence of axons being torn apart, but their axolemma is damaged by the stretching and compression forces. This allows calcium to enter the axon, activating proteases that damage the intracellular structures (neurofilaments and microtubules) necessary for axoplasmic transport. Transport products accumulate, resulting in axonal swelling, lobulation, and ultimately transection with formation of the classic *retraction ball* over the course of the first day or two. Over the ensuing weeks and months attempts at regrowth and regeneration can be observed, with sprouting from the proximal segment. Damaged axons can be seen lying adjacent to intact fibres. The observation that diffuse axonal injury takes hours to develop, rather than being an irreversible effect of the impact itself, lends support to the maxim that care of the patient in the first few hours following a severe injury is critical to outcome.

The β -amyloid precursor protein (β APP) is transported along axons but only becomes detectable by immunocytochemical staining when the axonal transport systems are disrupted and it accumulates. It has been used as a sensitive marker for diffuse axonal injury; β APP staining is evident within 1–2 hours of injury and can then be used to track the axonal swelling and formation of axonal bulbs over the first few hours after injury (McKenzie *et al.* 1996; Wilkinson *et al.* 1999). High levels are found following closed head injury, for example due to falls (Abou-Hamden *et al.* 1997). β APP staining has broadened the concept of diffuse axonal injury; it is observed before changes are observed on routine histopathology using silver staining (Geddes *et al.* 2000). However, the greater sensitivity of β APP staining has come at the expense of less specificity; it is to be found in many patients without TBI, for example in those dying from opiate overdose (Niess *et al.* 2002). This may be explained by the finding that anoxic brain injury produces β APP staining, although the pattern of staining is probably different from that in TBI (Kaur *et al.* 1999). Therefore some now distinguish traumatic diffuse axonal injury from other causes of diffuse axonal injury.

Neuronal death

To understand the processes leading to cell death after TBI it is useful to distinguish necrotic from apoptotic mechanisms (Povlishock & Katz 2005), although the cellular mechanisms involved probably overlap and elevated intracellular calcium is common to both. Both involve neurones and glia. Necrotic cell death is produced by cellular disruption, either from the destructive forces of the trauma on the cell membrane or due to ischaemia for example related to intracerebral contusion/haemorrhage. Necrotic cell death is rapid and relatively passive, with swelling of cytoplasm and mitochondria. Various processes may contribute, including the toxic effects of excitatory neurotransmitters, particularly glutamate (Faden *et al.* 1989), mitochondrial dysfunction (Robertson 2004), calcium activation of proteases and phospholipases, formation of toxic free radicals and low intracellular magnesium. Immunological processes may also be involved (Schmidt *et al.* 2005), including activation of interleukins (Tasci *et al.* 2003).

On the other hand, apoptosis, or programmed cell death, is a much more active process with a variety of triggers, including ligand binding to specific cell death receptors on the surface of the cell (e.g. FAS), resulting in alterations of the balance within the cell of pro- and anti-apoptotic pathways, in particular the Bcl-2 family of proteins. Caspases, which cleave proteins, are central to the pathways causing cell death, one of which involves the activation of endonucleases that attack the cell's DNA, producing DNA fragments. Terminal deoxynucleotide transferase-mediated nick end labelling (TUNEL) of DNA fragments allows apoptotic cells to be identified histochemically. Evidence of apoptosis is seen in the majority of patients after severe injury, much of it within white matter as early as 45 minutes after injury, maximal at a few days and sometimes lasting over a year (Smith *et al.* 2000; Williams *et al.* 2001; Hausmann *et al.* 2004; Wilson *et al.* 2004). Studies examining tissue taken in the course of therapeutic evacuation of severe contusions have demonstrated changes in the pro-apoptotic proteins Bax and caspase, and the anti-apoptotic protein Bcl (Ng *et al.* 2000; Nathoo *et al.* 2004); patients lacking Bcl had worse outcome. Tissue taken at surgery has also demonstrated upregulation of the FAS receptor death-inducing signalling complex within a few hours of injury (Qiu *et al.* 2002), and expression of c-Fos and c-Jun mRNA, which may relate to activation of apoptotic pathways, with greater expression associated with worse outcome at 1 year (Whitfield & Pickard 2000).

Both necrotic and apoptotic cell death are seen in focal injury, e.g. contusions, with necrotic cell death being predominant in the core of the damaged area, and apoptotic cell death being observed in the pericontusional zone (Liou *et al.* 2003; Hausmann *et al.* 2004). Of special interest is the diffuse neuronal death seen throughout the brain but particularly in the cortex, hippocampus (Maxwell *et al.* 2003) and diencephalon. This may be due to anoxia associated with the

trauma, but animal models suggest that mechanical disruption to the membrane is also involved, triggering both necrotic and apoptotic pathways. However, axonal transection, due to diffuse axonal injury, does not necessarily cause the neuronal soma to die. On the other hand, neurotrophic factors may counter the effects facilitating cell death (Chiaretti *et al.* 2003).

Other sequelae

Ventriculomegaly

Enlargement of the lateral ventricles, and to a lesser extent the third and fourth ventricles, is common after severe TBI (Mazzini *et al.* 2003). Usually regarded as due to cerebral atrophy, particularly of white matter, a key clinical question is whether ventriculomegaly is in fact, in that particular patient, due to blockage of the free flow of CSF, with or without elevated intracranial pressure. This is discussed further in the section on neuroimaging.

Effects on cerebral metabolism

In the immediate aftermath of brain injury, post-traumatic biochemical changes (see above) are likely to increase metabolic demand. Alcoholics will be particularly at risk; in hospital they will effectively be in an alcohol withdrawal state, known to increase the metabolic activity of the brain, in the first few days after injury. It has been suggested that a common pattern after head injury is for there to be normal or low flow rates in the first 24 hours, succeeded by relative hyperaemia ('luxury' perfusion) that may persist for many days (Overgaard & Tweed 1974). Correspondingly, increased cerebral glucose uptake is found in the first 3–4 days after severe brain injury (Bergsneider *et al.* 1997). This is then followed by somewhat reduced uptake 1–3 weeks after injury and then gradual recovery over the course of 1 year (Bergsneider *et al.* 2001). However, similar changes in glucose uptake are seen in mild head injury (Bergsneider *et al.* 2000), suggesting that the causes of the changes in glucose uptake are multifactorial. For example, intraparenchymal haemorrhagic lesions may produce increased or reduced uptake.

Global reductions in blood flow after head injury are associated with worse outcome (Bouma *et al.* 1991). Oxygen delivery is further jeopardised by poor diffusion from the capillary to the cell (Menon *et al.* 2004). Disordered autoregulation (Nortje & Menon 2004) may contribute to a mismatch between cerebral blood flow and metabolism. Patients with very severe injury show reduced oxygen and glucose utilisation in grey matter (Glenn *et al.* 2003). Those with lower cerebral metabolic rates have worse outcomes, and reductions in deep structures relate to prolonged coma. In white matter, a mismatch between increased glucose metabolism but without increased oxygen consumption may be seen (Wu *et al.* 2004).

A β peptide deposition

Of interest to the proposal that head injury may be a risk factor for Alzheimer's disease (see Chapter 9) is the observation that A β peptides, which are produced by cleavage of β APP (see above) and which aggregate to form β -amyloid protein, have been found to accumulate in about 30% of patients after TBI and may form plaques (Roberts *et al.* 1994; Ikonomic *et al.* 2004), similar to those seen in Alzheimer's disease. However, some groups have failed to find elevated A β after head injury (Adle-Biasette *et al.* 1996; Macfarlane *et al.* 1999).

The $\epsilon 4$ allele of apolipoprotein E (ApoE) is known to be a risk factor for Alzheimer's and other neurological diseases, perhaps related to effects on A β metabolism. Several studies have therefore looked at the relationship between ApoE $\epsilon 4$ status and head injury outcome. Most studies that have examined this have found that $\epsilon 4$ -positive status (whether

homozygous or heterozygous) is associated with worse outcome (Table 4.1). Two large prospective studies have failed to find an effect in both mild (Chamelian *et al.* 2004) and more severe (Teasdale *et al.* 2005) head injuries, but in moderate to severe injury the evidence overall does suggest that those who are ApoE $\epsilon 4$ positive do worse, both in terms of early and late outcomes.

Cell regeneration/plasticity

It is now evident that cells in the adult mammalian brain can divide and develop into new neurones, particularly in the hippocampus and subventricular zones, but also in the neo-cortex (Magavi *et al.* 2000) and that these cells can form long-distance corticothalamic connections. There is evidence of cell proliferation in rat brain after TBI, although no evidence of development of neurones was found (Chirumamilla *et al.* 2002). These findings are of interest to human recovery from

Table 4.1 Apolipoprotein (Apo)E status and outcome after head injury.

	Mild	Mixed/uncertain	Moderate/severe
Early effects	Worse on speed measures (PASAT and Pegboard) at 3 weeks* (1)	No difference on GOS [†] (17)	Longer loss of consciousness* (2) Increased haematoma volume on CT brain scan* (3)
Intermediate outcome months post injury	No difference on various measures including GOS, neuropsychological battery, RPCSQ [†] (11)	Greater disability scores on motor items of FIM but not cognitive* (6)	Fewer with good outcome at 6 months (1 of 27 vs 13 of 42)* (2) More severe disability* (2) More poor outcome (dead/severe disability) (10 of 19 vs 21 of 81) (note more alcohol at time of injury)* (7) Late post-traumatic seizures: relative risk 2.4 (95% CI 1.15–5.07)* (12) No difference GOSE [†] (14)
Late outcome years post injury	Do worse on divided attention, recognition of faces and recall of actions* (4) More chronic traumatic encephalopathy in high-exposure boxers* (5) More older active football players in impaired range on general cognitive functioning (3 of 5 vs 1 of 11)* (16)	Worse impairment of memory but not executive function* (8) More dementia* (9, 15) No difference in risk of dementia [†] (13, 14)	Trend towards fewer with good late outcome (22% vs 30%; $P = 0.084$)* (10)

* Patients who are positive for the ApoE $\epsilon 4$ allele do worse than those who are ApoE $\epsilon 4$ negative. Note that patients who are ApoE $\epsilon 4$ positive can be heterozygous or homozygous.

[†] Patients who are ApoE $\epsilon 4$ positive do not have a different outcome from those who are ApoE $\epsilon 4$ negative.

TBI, suggesting the potential for improved recovery if these regenerative pathways can be facilitated.

In animal models of TBI, neurones demonstrate plasticity, in terms of sprouting of new dendrites but also in terms of synaptic reorganisation involving both pruning and new synapse formation.

Neurotransmitters

The effects of head injury on catecholamine pathways are not well defined. Animal models have suggested greater reductions in dopamine than noradrenaline (norepinephrine) function particularly in frontal lobes. A clinical study of the positive effect of a dopamine agonist on executive function supports this suggestion (McDowell *et al.* 1998). In patients with very severe brain injury it has been suggested that lesions around the substantia nigra may cause parkinsonism (Matsuda *et al.* 2003). Single photon emission computed tomography (SPECT) has found evidence of dopamine transporter loss in striatum after TBI, indicating presynaptic dopamine loss (Donnemiller *et al.* 2000). Evidence for involvement of serotonergic systems in humans is inconsistent, with elevated and/or reduced levels of serotonin metabolites being found in CSF.

A more consistent story is emerging for acetylcholine. Elevated levels are consistently found in CSF early after injury. In the long term, reductions in choline acetyltransferase, the presynaptic marker of cholinergic neurones, are found in cortex (Murdoch *et al.* 1998) without changes in postsynaptic nicotinic or muscarinic receptors. These findings tally with histological evidence of damage to the nucleus basalis of Meynert (Murdoch *et al.* 2002) and more recently with MRI evidence of reduced grey matter density of basal forebrain (Salmond *et al.* 2005), the basal forebrain being the location of the nucleus basalis of Meynert and the septal nuclei, the main cholinergic nuclei and source of presynaptic neurones.

Peripheral markers of cell damage

It would be useful, particularly for those with milder injuries, to have a serum or plasma assay that was a marker of the degree of cerebral damage after a head injury and which could thereby help predict outcome. Several have been proposed but it seems that S-100B, a protein derived from glial cells, is the best candidate. Blood levels of S-100B taken within a few hours or days after injury may be a useful marker of the degree of cerebral damage. There is certainly good evidence in moderate to severe head injury that higher S-100B levels predict worse outcome in terms of both morbidity (Dimopoulou *et al.* 2003; Pelinka *et al.* 2004) and disability measures between 1 month and 1 year after injury (Raabe & Seifert 2000; Rothoerl *et al.* 2000; Townend *et al.* 2002). For mild head injury the picture is more equivocal, with several studies failing to find an early outcome effect (Ingebrigtsen *et al.* 1999, 2000; de Boussard *et al.* 2005; Stapert *et al.* 2005), whereas others find that higher S-100B levels are

associated with neuroimaging evidence of brain injury (Ingebrigtsen *et al.* 1999, 2000) or symptoms/handicap in the first few weeks or months (De Kruijk *et al.* 2002a; Stranjalis *et al.* 2004) or as late as 1 year after injury (Waterloo *et al.* 1997; Stalnacke *et al.* 2005). Despite these largely positive associations between S-100B levels and outcome, it is possible that levels are associated with extracranial injury rather than brain injury. For example, elevated levels have been found in those with severe extracranial injury without good evidence of head injury (Savola *et al.* 2004); one study has shown elevated levels after running a marathon (Hasselblatt *et al.* 2004). In conclusion, as it stands, S-100B measured in the blood is not a useful marker of brain injury severity in the individual patient; in those with mild head injury the results are too inconsistent; and in those with more severe injury the extent of the injury will be self-evident from standard clinical measures and there is no evidence that S-100B level adds value to these observations.

The importance of these discoveries lies in the promise they offer for the development of neuroprotective agents, several of which have been found to be effective in animal studies. However, clinical studies have been disappointing, perhaps reflecting the much greater heterogeneity, both of the head injury and the nature and timing of treatment, found in the clinical setting compared with the well-controlled and optimised laboratory setting. For example, steroids early after injury might be expected to be effective given the evidence for the deleterious effects of activation of inflammatory pathways. However, in practice steroids do not work (Edwards *et al.* 2005). At present early sedation and ventilation, with good control of blood gases, blood pressure and intracranial pressure, seem to be the most important acute treatment strategies for severe head injury.

Electroencephalogram after head injury

Bickford and Klass (1966) review the EEG alterations seen after head injury. One of the most sensitive changes is local suppression of alpha rhythm in the region of a localised blow or in the contrecoup area. The degree of impairment of alpha rhythm in the early days after injury may predict outcome (Vespa *et al.* 2002). With severe injury, delta waves at 1–3 Hz appear and may persist for several weeks or months. During recovery there is a gradual trend towards increase of frequency and normality over the weeks and months that follow.

The EEG can be helpful in the differential diagnosis of the unconscious patient, chiefly by pointing to causes other than head injury that might be overlooked. Fast activity may suggest drug overdosage, marked localised delta activity will point to a primary intracerebral lesion, and spike-and-wave bursts will indicate an epileptic process. The EEG can also draw attention to complications following head injury.

With regard to prognosis, less can be said with certainty. The degree of overall EEG abnormality is not a firm guide and must always be taken in conjunction with other clinical data. Some suggest that cognitive event-related potentials or quantified EEG may be useful in determining the organic contribution to symptoms after mild brain injury (Gaetz & Bernstein 2001). However, most have not found these investigations to be clinically useful. This is perhaps not surprising given the evidence that a normal EEG may be associated with worse prognosis in those with persistent symptoms after less severe head injury (Williams 1941; Muller 1969). Nevertheless, serial recordings may be helpful, especially in revealing the organic component in cases thought to be due entirely to psychogenic factors. The EEG is unreliable as a guide to the later development of epilepsy, some 50% of patients who develop post-traumatic epilepsy having normal or only minimally abnormal EEGs initially. Jennett (1975) found no consistent correlation between EEG abnormalities during the first year after injury and the development of late epilepsy. However, a persistent EEG focus 1 month after injury is a risk factor for post-traumatic epilepsy (Angeleri *et al.* 1999).

Neuroimaging and head injury

Computed tomography has proved invaluable in the hours and days after injury in displaying the neuropathological effects of head injury and in serving as a guide to surgical intervention. Acute mass effects are revealed by shift of the midline structures or compression of the midbrain cisterns. Extradural, subdural and intracerebral haematomas as well as areas of contusion and oedema are shown. In the later stages ventricular enlargement may become apparent, along with focal or generalised atrophy. With severe injuries only some 5% yield scans that can be considered normal in all respects (Eisenberg & Levin 1989). Findings on a CT brain scan may contribute to the assessment of head injury severity (Marshall *et al.* 1991).

Compared with CT, MRI is more sensitive at revealing brain pathology but is less suited to the investigation of patients in the acute stages, especially when on life support equipment. Moreover, the superiority of MRI does not lie in matters likely to influence acute surgical management (Fiser *et al.* 1998). Nonetheless, the yield from MRI greatly exceeds that from CT; this partly reflects the intrinsically greater sensitivity of MRI, but also the location of lesions in TBI. Contusions tend to occur at the brain–bone interface, the soft brain becoming traumatised against the bone (see Fig. 4.1). Bone is very much more radiodense than soft tissue and this may result in imaging artefacts adjacent to the inner surface of the skull, making it difficult to detect lesions at this interface (see Fig. 4.7). Given that these contusions may have important implications for later neuropsychiatric sequelae, MRI is the preferred imaging technique in this situation. In the chronic stages MRI is also

superior to CT in the detection of white matter changes consequent on diffuse axonal injury (Kelly *et al.* 1988; Mittl *et al.* 1994). However, it is important to bear in mind that as the sensitivity of imaging increases, so too the likelihood that a subtle abnormality will be found that is unrelated to the injury. For example, on T2-weighted imaging, non-specific white matter hyperintensities are found in healthy control subjects; the older the subject, the more likely they are to be seen.

Certain clinicopathological correlations have emerged. Severity of injury, as judged by degree and duration of consciousness, is related to both the number and location of MRI lesions (Jenkins *et al.* 1986). Their depth from the cortical surface was found to increase with severity, reinforcing the view that the brain is injured concentrically inwards from the surface in closed head injury. Only one of 50 patients showed a brainstem lesion, compared with 46 showing hemisphere damage, suggesting that white matter hemispheric lesions may be the primary event in traumatic loss of consciousness. Similarly in children, deeper lesions are seen with more severe injuries (Grados *et al.* 2001).

Levin *et al.* (1987a) noted the frequency of MRI lesions in the frontal and temporal regions, both areas that are often neurologically silent. Deficits on neuropsychological testing in the acute stage were related to size and location of such abnormalities, for example perseveration with frontal involvement, and memory difficulties with temporal lesions. At follow-up, MRI in individual patients could be informative, for example in a patient whose left frontal haematoma and diminished verbal fluency were observed to resolve together.

Wilson *et al.* (1988) examined the relationship between MRI lesions and outcome. Patients were scanned in the acute stages and then at follow-up 5–18 months later. Measures of neuropsychological outcome showed a strong correlation with the abnormalities that persisted, especially those in the deeper brain regions. Ventricular enlargement on follow-up correlated strongly with residual neuropsychological disability. Cerebral atrophy, as demonstrated by ventricular enlargement or reduction in brain volume, in the chronic phase after injury has consistently been found to be associated with poor outcome, both using CT (Levin *et al.* 1981; Timming *et al.* 1982; Reider-Groswasser *et al.* 1993) and MRI (Blatter *et al.* 1997). At least some of the atrophy that follows severe TBI may be due to hypoxia in the immediate post-injury period (Ariza *et al.* 2004).

Volumetric measurements of grey and white matter have enabled more detailed analysis of the contributions of atrophy of different regions to outcome. Atrophy of corpus callosum is frequently found (Levin *et al.* 1990a), sometimes with high signal on fluid-attenuated inversion recovery (FLAIR) sequences (Ashikaga *et al.* 1997), and is associated with more severe injury (Yount *et al.* 2002; Tomaiuolo *et al.* 2004) and worse outcome (Takaoka *et al.* 2002). An attempt to demonstrate an association between slowed interhemi-

spheric transfer of information and the extent of corpus callosal atrophy was not successful (Mathias *et al.* 2004a), although generalised white matter atrophy was associated with slowed information processing. Enlargement of the third ventricle predicts poor outcome (Bigler *et al.* 1999; Henry-Feugeas *et al.* 2000; Groswasser *et al.* 2002), perhaps because it is a marker of severe frontal white matter injury. Much of the ventriculomegaly and sulcal enlargement is explained by white matter atrophy (Bigler *et al.* 2002); thus temporal horn enlargement may be explained more by white matter atrophy in the temporal lobe than by hippocampal atrophy. Yet hippocampal atrophy is a fairly consistent finding (Bigler *et al.* 1997; Arciniegas *et al.* 2001) and correlates with memory impairment (Tomaiuolo *et al.* 2004). Studies of grey matter have found generalised cortical atrophy as well as more specific atrophy or reduced grey matter density of cingulate gyrus, thalamus and basal forebrain, as well as hippocampal and cerebellar atrophy (Gale *et al.* 2005; Salmond *et al.* 2005).

There is some evidence that atrophy is likely to be greater in those with drug or alcohol abuse (Bigler *et al.* 1996; Barker *et al.* 1999; Wilde *et al.* 2004), which is unsurprising given the potential for alcohol itself to produce cerebral and cerebellar atrophy. However, in one of these studies the group with drug and alcohol abuse had more severe injury as measured by the Glasgow Coma Scale (GCS) than those without abuse, and once this was controlled for there was no evidence for greater atrophy in the drug and alcohol group. In this case it might be argued that one reason those with alcohol abuse had more severe GCS scores was because they were more likely to be intoxicated at the time of injury, and that it was the intoxication rather than greater injury severity that produced the lower GCS scores. A history of prior alcohol abuse may produce selective reduction of frontal grey matter volume (Jorge *et al.* 2005).

While reasonable correlations between cerebral atrophic changes and injury severity and outcome are found consistently, it is less certain that they add much to outcome prediction over and above standard clinical measures; for example van der Naalt *et al.* (1999a) found that when it came to predicting outcome at 1 year, once the duration of post-traumatic amnesia (PTA) had been taken into account, findings on CT and MRI were not particularly helpful.

It has been even more difficult to demonstrate clear associations between lesion location and outcome (Markowitsch & Calabrese 1996; Azouvi 2000). This may well reflect the high degree of intercorrelation between lesions (Wilson, J.T. *et al.* 1992), the diffuse nature of the injury in closed head injuries, and that brain which appears normal on neuroimaging may nevertheless be damaged (see studies on diffusion-weighted imaging at the end of this section). Bigler (2001) described three cases with left frontal injuries but all with very different neuropsychological outcomes. In a review of brain imaging findings that relied heavily on CT studies, Wilson (1990)

showed that greater damage to left hemisphere was associated with greater impairment on measures of intellectual damage, particularly for verbal material. Injury was almost always more severe anteriorly, and this frontal injury was best at predicting outcome (van der Naalt *et al.* 1999a; Pieralini *et al.* 2000). The adverse effects of frontal and temporal injury have been documented using CT imaging. Levin *et al.* (1987b), using the Neurobehaviour Rating Scale in patients with closed head injury, showed that symptoms which clinicians attribute to frontal injury (e.g. disinhibition, poor insight and unrealistic planning) were more common in patients with CT evidence of frontal lesions compared with those with lesions confined to the extrafrontal region. Those with frontotemporal lesions show more executive impairment (Lehtonen *et al.* 2005), although this did not result in any worse community participation at 1-year follow-up.

Early agitation (van der Naalt *et al.* 2000), aggression (Tateno *et al.* 2003) and behavioural problems (Wallesch *et al.* 2001) have been found to be associated with frontal injury. However, in mild TBI it may be more difficult to relate MRI findings to the effects of the injury (Hughes *et al.* 2004). Abnormalities on MRI were found in 26 of 80 patients with mild TBI, but in only five of the patients were they definitely post-traumatic; there was no significant correlation with outcome.

The discussion thus far has focused largely on MRI findings using routine T1, T2 and FLAIR sequences. Despite being more sensitive than CT brain imaging, the routine MRI brain scan may nevertheless be normal, or only show limited focal injury, in somebody whose symptoms suggest quite widespread cerebral injury. Are there other magnetic resonance techniques and imaging sequences that enable the detection of brain injury in the normal-appearing brain? Gradient echo sequences are particularly good at picking up the signal from paramagnetic material, including iron. It is therefore a sensitive technique for detecting haemosiderin left behind after intracerebral haemorrhage (Fig. 4.4; see also Fig. 3.14), identifying lesions not seen on routine T2 sequences (Di Stefano *et al.* 2000; Wardlaw & Statham 2000). This is particularly the case for small haemorrhages of diffuse axonal injury, where three times as many lesions are found on gradient echo as routine T2 images (Scheid *et al.* 2003), and at least some of these probably have functional consequences (Yanagawa *et al.* 2000). Lesion load measured using gradient echo may be a better predictor of PTA duration than standard T2 sequences (Gerber *et al.* 2004). Therefore gradient echo sequences should be requested, particularly in cases of mild injury where the evidence of diffuse axonal injury might otherwise be missed. However, it should not be forgotten that small intracerebral haemorrhages may be observed using gradient echo in perhaps 5% of otherwise healthy elderly patients (Symms *et al.* 2004). On the other hand, 20% of low-signal foci, consistent with intracerebral haemosiderin deposits from old haemorrhage, identified

Fig. 4.4 Gradient-echo MRI images identify old haemorrhage. A 62-year-old man fell 4 metres and hit his head. There was possibly no loss of consciousness, but he was sedated and ventilated for 4 hours, and confused and agitated for several days. His post-traumatic amnesia lasted about 2 weeks. He made a good recovery by 2 months, although he was left with personality change such that he was slightly

less aware of safety. A CT brain scan was performed on the day on the injury and an MRI brain scan 2 months later. (a) CT brain scan shows left frontal haemorrhages; (b) MRI T2 image shows some probable high signal in left frontal white matter and small low signal further anteriorly; (c) MRI gradient-echo image with easily visible low signal at sites of old haemorrhage.

in the first year after injury using gradient echo MRI, are no longer detected 2 years after injury (Messori *et al.* 2003). Therefore normal gradient echo scans, particularly some time after injury, cannot exclude previous haemorrhage.

Magnetisation transfer imaging (MTI) and diffusion-weighted imaging (DWI) have found abnormal signal in normal-appearing white matter after TBI (reviewed in Symms *et al.* 2004). In patients with mild TBI and normal MRI, as well as others with more severe injury, abnormalities of corpus callosum and other white matter tracts may be found (Sinson *et al.* 2001; Arfanakis *et al.* 2002; Inglese *et al.* 2005). DWI is particularly useful for studying white matter tract integrity. Apparent diffusion coefficient (ADC) may be reduced early after injury in the corpus callosum, perhaps reflecting cellular oedema (Liu *et al.* 1999). Increases in diffusivity have been found in professional boxers, of whom more than 50% had normal routine MRI scans (Zhang *et al.* 2003), and in two patients with severe TBI in normal-appearing white matter (Rugg-Gunn *et al.* 2001). In those with more severe injury, abnormalities detected by DWI in the early days after injury may predict outcome, worse outcome being associated with reduced fractional anisotropy (Ptak *et al.* 2003). Changes in ADC, either measured using the mean value for whole brain (Shanmuganathan *et al.* 2004) or lesion volume detected using ADC maps (Schaefer *et al.* 2004), were better predictors of injury severity and outcome respectively than were standard MRI measures.

Development of ventriculomegaly and hydrocephalus

One question of interest is the evolution of neuroimaging changes over time. Early CT brain imaging over the first few hours and days after injury may show the gradual bleeding into contusions, which become larger and more radiodense.

However, of more interest to the assessment of late symptoms is the distinction between those changes that occur with normal recovery and those which may reflect secondary complications. In particular it is important to know the time course of the ventriculomegaly that accompanies cerebral atrophy: are increases in ventricular volume due to the development of post-traumatic hydrocephalus, which requires shunting, or can they be accepted as the changes normally observed due to atrophy as brain tissue dies and is resorbed? Unfortunately, there is uncertainty as to whether later enlargement, after the first few weeks, is more likely to represent hydrocephalus that may require shunting, or ventriculomegaly due to progressive cerebral atrophy. One study has suggested that early enlargement, before 1 month, is more likely to be due to obstruction of CSF (Meyers *et al.* 1983), whereas another (Marmarou *et al.* 1996) suggested that later enlargement, progressing beyond 1 month, was more likely to be associated with hydrocephalus than atrophy. Subarachnoid or intraventricular bleeding and meningitis at the time of the trauma are risk factors for hydrocephalus.

Very divergent rates are offered for the proportion of patients whose ventricular enlargement is due to hydrocephalus as opposed to atrophy (Guyot & Michael 2000). In one study 45% of patients with ventriculomegaly within 3 months of a severe head injury were found to have hydrocephalus, defined by increased resistance to CSF outflow or raised intracranial pressure (Marmarou *et al.* 1996). However, in other series of severe head injuries less than 2–3% were diagnosed as having post-traumatic hydrocephalus (Lee *et al.* 1998; Matsushita *et al.* 2000). This latter figure is perhaps more consistent with the finding that surgery for post-traumatic ventriculomegaly may not improve outcome (Fu *et al.* 2002). It must also be remembered

that a good proportion of hydrocephalus remits spontaneously (Front *et al.* 1972). Therefore most would not proceed to surgery unless there was good clinical evidence (e.g. deteriorating clinical state) that hydrocephalus was pathogenic. The estimate of Cardoso and Galbraith (1985) that about 0.5% of severe head injuries may benefit from shunting may be more realistic than the 10% that some authors have suggested (Mazzini *et al.* 2003). Nevertheless, hydrocephalus needs to be excluded before a diagnosis of vegetative state is made and here CSF studies may be critical in determining who will benefit from shunting (Pickard *et al.* 2005).

The clinical syndrome of a post-traumatic progressive dementia, with or without deteriorating incontinence and gait ataxia, that responds to shunting is very rare but needs occasionally to be considered, particularly if there are risk factors for hydrocephalus. Brain imaging not only excludes a subdural haemorrhage but also allows the present state of the ventricles to be compared with previous findings, or act as a baseline to determine any future change in ventricular size.

However, a moderate progressive increase in size of the ventricles, months and even years after injury, does not necessarily indicate the presence of hydrocephalus as a secondary complication. Progressive atrophy may take place over many years. Blatter *et al.* (1997) studied 123 patients, mostly with moderate to severe injury, who had MRI brain scans at different time intervals after injury; based on the injury to scan interval they were divided into five groups with different post-injury intervals, and the mean scores for each group plotted against their mean time after injury. Correcting for age, sex and head size, the images were analysed to determine the volumes of CSF spaces and total brain and these were then compared with controls without head injury. On the time-dependent plot of standardised brain volume the greatest reduction was seen between the groups measured at a mean of 13 and 42 days after injury, respectively (Fig. 4.5). This was matched by proportionally larger increases in CSF volume, most evident in temporal horn. Further increases in ventricular volume were not observed in the groups with

post-injury intervals greater than 136 days. Reductions in brain volume were seen across the later groups, but beyond 310 days after injury the reductions were hardly greater than those predicted by reductions in brain volume seen with normal ageing (0.26% per year). Whereas reductions in brain volume were only of the order of 2–3%, increases in ventricular volume (lateral, third and temporal horn) were of the order of twofold to threefold. Despite the limitations of this study it does match clinical experience; the vast majority of cerebral atrophy is to be found within the first 6 months after injury. MacKenzie *et al.* (2002) examined repeat MRI scans in seven patients with mild to moderate head injury; on average the first scan was 125 days after injury and the second 350 days, although there was a large range of post-injury intervals. The rate of reduction in brain volume over time was three to four times faster than seen in four controls with repeat scans. Neither of these studies reported whether the patients were abusing alcohol or drugs, which could have been a confounder.

Functional neuroimaging: studies of cerebral blood flow and metabolism

Single photon emission computed tomography scanning, usually using hexamethylpropyleneamine oxine (HMPAO) to measure blood flow, has been shown to complement the information obtained with CT or MRI, and indeed to reveal additional areas of cerebral damage that correlate with clinical signs (Newton *et al.* 1992). Nineteen patients undergoing rehabilitation between 3 months and 3 years after injury were subjected to all three investigations. A total of 43 perfusion deficits were shown by SPECT, compared with 21 focal lesions on MRI and 13 on CT. Of these 43 lesions, 31 were not apparent on either CT or MRI. The number of SPECT lesions correlated significantly with the Glasgow Outcome Score. Lesions shown by SPECT, but not apparent on CT or MRI, sometimes revealed important clinical correlations. One patient, for example, was left with reading difficulties 5 months after injury; the only abnormal finding was on SPECT which showed a perfusion defect in the left poste-

Fig. 4.5 Changes in normalized brain volume measured using MRI. Changes over time are corrected for differences in age, sex and head size using data from a normative database. Note that this is not a longitudinal study but consists of multiple cohorts each at different times after injury. (From Blatter *et al.* 1997 with permission.)

rior parietal region. Similar findings have been reported more recently, with hypoperfusion in the frontal lobes being associated with personality change (Kinuya *et al.* 2004). However, not all studies have found SPECT to be more sensitive than MRI (Stamatakis *et al.* 2002), perhaps because some of the hypoperfusion evident in early SPECT scans will resolve, whereas structural changes are more enduring. Nevertheless, several studies have demonstrated areas of hypoperfusion using SPECT in patients with mild TBI and persistent symptoms and with little evidence of injury on CT or MRI (Kant *et al.* 1997; Umile *et al.* 2002; Bonne *et al.* 2003; Korn *et al.* 2005). For example, one study found almost 60% of such patients to have abnormalities on SPECT (Abu-Judeh *et al.* 1999). A recent study prospectively examined patients within 72 hours of a mild head injury and found 63% to have abnormalities on technetium-99m ethylcysteinate dimer (^{99m}Tc-ECD) SPECT (Gowda *et al.* 2006), although there was also a surprisingly high rate (34%) of patients with CT scan lesions. In patients with anosmia after trauma, SPECT (Varney & Bushnell 1998) or positron emission tomography (PET) (Varney *et al.* 2001) may demonstrate hypoperfusion of the orbitofrontal cortex, although these studies both come from the same research group and await confirmation.

Ruff *et al.* (1989) attempted to demonstrate the value of PET when neuropsychological deficits persisted in the presence of normal CT and MRI scans. Six such patients were scanned 3–5 years after injury, and anterior frontal hypometabolism was shown in five. Some of the patients in this study had suffered minimal injuries and the significance of the hypometabolism in such cases should perhaps be viewed with caution. Although these findings may be taken to indicate evidence of brain injury only disclosed by SPECT or PET, it is important to remember that cerebral hypoperfusion may be found in patients without brain injury but with for example depression or schizophrenia.

Studies with PET, using either H₂¹⁵O to measure blood flow or ¹⁸F-FDG (fluorodeoxyglucose) to measure cerebral metabolic rate, generally corroborate these SPECT findings. For example, reductions in cerebral metabolic rate in thalamus and brainstem in the days after injury are greater in those who remain in coma (Hattori *et al.* 2003; Nakayama *et al.* 2006), many of these patients showing no abnormality on CT or MRI. One study by Fontaine *et al.* (1999) has suggested that the localisation of hypometabolism detected using FDG PET in the resting state in patients with severe TBI, but without major focal abnormalities on MRI, correlates with their mental state. Those with executive and memory difficulties were more likely to demonstrate hypometabolism in lateral and medial prefrontal areas, whereas medial prefrontal and cingulate areas were affected in those with behavioural disorder. A single case study found reduced hippocampal and anterior cingulate metabolism in a patient with a relatively isolated prolonged retrograde amnesia (RA) (Mattioli *et al.* 1996). Patients with mild TBI may (Gross *et al.* 1996) or may not (Chen *et al.* 2003) show changes in cerebral

metabolic rate in the resting state, although in the latter study smaller increases in cerebral blood flow were found on a spatial working memory task. Patients with more severe injury also show changes in the pattern of cerebral metabolic response to task demand. For example, on a memory retrieval task they showed more widespread activation with less asymmetry of cerebral activation and less activation of dorsomedial thalamus, known to be involved in normal memory retrieval (Levine *et al.* 2002). Whether or not patients show greater or lesser activation than controls may depend on the task. Smaller increases in regional cerebral blood flow in the frontal lobe were seen during free recall on a verbal memory task, whereas during the recognition phase of the same task there was greater activation than seen in controls (Ricker *et al.* 2001).

Functional MRI (fMRI) studies provide support for the thesis that cortical activation in response to cognitively demanding tasks tends to be more widespread after TBI. McAllister *et al.* (1999), studying patients with mild TBI, were the first to demonstrate this effect. Subjects performed the 'n-back' working memory task in which they listened to a string of letters and were asked to indicate when a currently presented letter matched a letter they had heard 0, 1 or 2 letters back in the string. Although the injured patients performed almost as well as controls, they showed a different pattern of cerebral activation. With the more demanding task (2-back), comparing it with the 1-back task, the brain-injured patients showed more extensive activation of frontal and parietal areas. A similar pattern was found in a single case with severe injury (Scheibel *et al.* 2003). In an fMRI study of patients with severe TBI using a modified version of the Paced Auditory Serial Addition Task (PASAT), patients made more errors and showed a more dispersed activation of cerebral cortex in frontal and temporal areas (Christodoulou *et al.* 2001).

The value of functional imaging in the assessment of individual cases is yet to be established, although the findings can be of interest. For example, Langfitt *et al.* (1986) showed how areas of hypometabolism often extend beyond the structural abnormalities.

A student was unconscious for 20 minutes after a fall, and MRI examination showed right frontal and temporal lobe contusions; CT showed the right frontal contusion only. PET scan 17 days later, when he was alert but slowed, demonstrated impaired glucose metabolism in the frontal poles and orbital cortex of *both* hemispheres and in both anterior temporal lobe regions. Six months later the right frontal and temporal damage was still evident on structural scans; metabolism had improved in both frontal lobes but the right was still impaired. The left but not the right temporal abnormality had recovered. At this stage he still complained of difficulty with concentration, and though performing well on IQ tests he was inattentive and slowed in conversation.

Magnetic resonance spectroscopy can give some insight into cerebral metabolism. For example, a low *N*-acetylaspartate to creatinine ratio is thought to be a marker of neuronal/axonal loss or damage. Several studies have measured this in white matter, including corpus callosum, in the days and months after TBI and found a reduced ratio (Cecil *et al.* 1998), which was associated with worse outcome (Friedman *et al.* 1998; Garnett *et al.* 2000; Sinson *et al.* 2001). Reductions in *N*-acetylaspartate in grey matter may also correlate with outcome (Brooks *et al.* 2000).

Acute effects of head injury

The most constant of the acute effects of head injury is impairment of consciousness, ranging from momentary dazing to prolonged coma. This is usually succeeded during recovery by a variable period of confusion, and the whole episode proves later to be surrounded by characteristic amnesic defects. These three features form the cardinal symptoms of the early effects of head injury. They provide important information about the severity of brain damage that is likely to have occurred, and must therefore be taken carefully into account when assessing prognosis. In addition, of course, there may be added effects due to damage to specific parts of the brain, and as a result of the various complications outlined above.

Impairment of consciousness

A good deal of debate has surrounded the definition of concussion. That given by Caveness and Walker (1966) is reproduced here: 'a clinical syndrome characterised by immediate and transient impairment of neural function, such as alteration of consciousness, disturbances of vision, equilibrium, due to mechanical forces'. Concussion can refer to any severity of head injury, from the mildest without loss of consciousness to the most severe with prolonged coma. However, in common usage concussion often implies a milder injury with absent or short-duration loss of consciousness and in which irreversible damage to neurones is slight or non-existent though neuronal dysfunction may last days or weeks.

Impairment of consciousness, however transient, follows all but the mildest blow in closed head injuries, and especially when the head is free to move at impact. There may be no detectable impairment of consciousness, but merely transient symptoms including muddled thinking, or disturbance of equilibrium and dizziness, or of vision or hearing; professional sportsmen refer to this constellation of symptoms as a 'ding' (Yarnell & Lynch 1973). Alternatively, there may be no outward sign of impairment of consciousness to onlookers, yet the patient has no recollection of the injury, showing that registration was failing to occur at the time. Loss of consciousness after penetrating head injuries is considerably

less common, also in static crushing injuries as already discussed.

In the typical case loss of consciousness is complete. The patient falls to the ground, displays no response to stimuli, and for a moment shows arrest of respiration, profound fall of blood pressure, pallor, dilated pupils, loss of corneal reflexes and paralysis of deglutition. There may be a period of flaccid paralysis with loss of tendon reflexes. With recovery, shallow sighing respiration is resumed and the circulatory state gradually returns to normal. Consciousness returns after a variable interval depending on the severity of injury. Usually this is followed by a period of confusion, drowsiness and headache, and sometimes by vomiting and dizziness. The duration of complete unconsciousness is often overestimated by the patient, because of the confusion that follows and the PTA which may greatly outlast the resumption of outwardly normal behaviour. Conversely, the patient may sometimes underestimate the period of unconsciousness or deny any knowledge of it.

In some, within 2 seconds of impact and lasting a few seconds there is mass contraction of the limbs often with arms held forward in a 'bear-hug' posture; this tonic phase may be followed by myoclonic jerking for a few seconds (McCrory *et al.* 1997). These concussive convulsions resemble epileptic seizures but there is uncertainty about their pathophysiology. They are not associated with an increased risk for post-traumatic epilepsy. By and large they are benign and some patients quickly regain consciousness and have little to show for the dramatic event.

Periods of unconsciousness lasting several hours are occasionally compatible with uneventful and complete recovery. However, the longer its duration and the deeper the level of coma, the more probable it is that permanent brain damage will have been sustained. Prolonged unconsciousness is more likely to be accompanied by evidence of brain damage on neurological examination, by evidence of raised intracranial pressure and by the presence of blood in the CSF. It is also more likely to be followed by a considerable period of post-traumatic confusion and by both physical and mental long-term sequelae.

The prolonged post-traumatic coma may be profound from the outset, or may deepen rapidly in the early stages due to intracerebral or subarachnoid bleeding. Decerebrate rigidity is common, with tonic fits, stertorous breathing, tachycardia and hyperpyrexia. Anoxia is a special hazard, resulting from obstruction of the airways or damage to the respiratory and vasomotor centres in the brainstem. Ominous signs of brainstem compression include muscular flaccidity, failing respiration, falling blood pressure and fixed dilated pupils. Skilled nursing and watchful medical supervision are therefore essential, with readiness to operate for extradural, subdural and intracerebral haematomas. Artificial aids to sustain respiration may be required for considerable periods of time, and electrolyte imbalance or anaemia due to

blood loss may need correction. In severe cases unconsciousness may persist for weeks or even months, and here permanent after-effects are to be expected. Lewin (1959) assessed the quality of recovery in 102 patients who had remained unconscious for over a month; 39 died, 15 were left very severely disabled, 29 made partial recoveries and 19 were ultimately well enough to return to their former work. If a good recovery was to be made, then some improvement was usually seen within the first month after injury: not necessarily return of consciousness but certainly increased responsiveness to pain or diminution of spasticity.

Post-traumatic delirium (post-traumatic confusional state) and post-traumatic amnesia

Post-traumatic delirium

As unconsciousness recedes the patient passes through a phase of impairment of consciousness with disorientation and impaired cognitive ability. This post-traumatic delirium (confusional state) shows much variation, depending on the severity of the injury and its complications, and coloured also by aspects of the patient's personality and present surroundings. In this stage there is always some degree of failure to retain new information. Accordingly, the period of post-traumatic delirium comes to be incorporated within the post-traumatic amnesic gap.

After momentary concussion a return to normal may be expected within a few minutes. After unconsciousness lasting several hours the ensuing disturbance may last for some days or weeks. In the most severe injuries, where permanent disablement is to follow, the phase of acute confusion may last for many months and ultimately shade into the picture of post-traumatic dementia. Thus there exists a fairly close relationship between severity of injury and duration of disorientation (Alderso & Novack 2002). However, exceptions are seen, since the severity of the delirium often depends on complicating factors such as anoxia, electrolyte disturbance, systemic infection or severe blood loss that need not lead to enduring brain damage. The dis-

turbance is usually more prolonged and severe in the elderly, those with cerebrovascular disease or with alcohol dependence.

The form which the disturbance takes is variable, ranging from apathetic withdrawal, through restless irritability, to florid delirious states. Fear, persecutory beliefs, and perplexity as in any delirium are common. There may be suspicious disbelief of the role and purpose of those around, such that nurses and other patients are thought to be spies or gaolers. More openly expressed delusions often originate in sensory falsifications and poverty of grasp. They are usually highly charged with emotion, changeable and unsystematised, and paranoid in content. Disorientation for time and place is marked at first. Cognitive dysfunction is also shown in difficulty with simple mental tests and obvious inability to concentrate or sustain mental effort. In many cases outward behaviour is little disturbed beyond obvious lethargy and failure of cognitive function. In these cases progress usually follows a torpid apathetic course until consciousness is fully regained.

As the confusional state improves, confabulations may come to dominate the mental state, almost always accompanied by lack of insight into the injury and its effects, and disorientation. The confabulating patient may be surprisingly upbeat and some are quite euphoric. Confabulation is often associated with misinterpretation of surroundings and misidentification of people. It is not unusual for patients to believe that staff or other patients on the ward are familiar to them, for example that their doctor is well known to them or that other patients are old friends. Very occasionally the misidentifications are described only on recovery. A bizarre state of double orientation may be maintained, or there may be reduplicative paramnesia with reduplications of place. Patients may believe they are still at work, even when they have not worked for many years before the injury. Alternatively, they may believe they are somewhere with emotional significance for them (see case study below). Such confabulatory delusional disorientation is particularly common in those with a history of alcohol dependence.

Confabulation and reduplicative paramnesia

(Bach *et al.* 2000)

G.O., aged 59, suffered a head injury in south London, probably due to an assault, with unknown duration of loss of consciousness. GCS score on admission was 11 and CT scan showed bilateral frontal contusions, particularly involving the orbitofrontal cortex, and anterior temporal lobe contusions. G.O. had spent much time in England but was resident in Italy living quite close to his daughter. At the time of the interview 6 months after the injury, in July, he had been an inpatient at the Maudsley Hospital in Camberwell in south

London, England, for about 3 months. There was some impairment of intellectual functioning, with a verbal IQ of 95 and performance IQ of 85, with moderate to severe impairments in memory and on executive tasks. He showed poor orientation to time and lacked insight into his impairment. For a period he had developed persecutory delusions, believing staff were plotting to kill him. About 2 weeks before the interview he had developed the belief that he was in hospital in Italy, and would occasionally speak to staff in Italian.

- S.F. What has led to your being in hospital now?
 G.O. I personally believe I was hit by a car in an alleyway where I was parked up behind my friend's flat.
 S.F. And how long ago was that?
 G.O. In the first week of May, 16 to 18 weeks ago.
 S.F. And where did the accident happen?
 G.O. It happened in England.
 S.F. And where are we now?
 G.O. We are now in Italy in a hospital.
 S.F. Where in Italy?
 G.O. Well I have tried over a dozen times to buy maps in order to ascertain this thoroughly for myself exactly where we are. Yes and everyone claims they don't have them, though they are eager for my custom, but once they have established what I want they send me down to the *caserma* [police station]. Because all the police there are English the police will sell me these or pass me on to the Italian equivalent of the Automobile Association.
 S.F. So this is all some sort of charade, masquerade?
 G.O. It's a charade, but a political charade.
 S.F. So we're somewhere in north, south Italy?
 G.O. In the north of Italy.
 S.F. And the evidence?
 G.O. Well now I know it because the ambulances are British. I have seen foot patrol on a couple of occasions of carabinieri.
- S.F. Just near here?
 G.O. Yes. But I have now heard on I suppose half a dozen times the sirens going as only an English one goes.
 S.F. So all the evidence is that we're in England, not Italy.
 G.O. Well it is now. I am totally convinced we're in a province of England.
 S.F. Yet located somewhere in north Italy?
 G.O. Yes.
 S.F. So we're not in south London?
 G.O. No.
 S.F. And are we in the Maudsley?
 G.O. We are in the Maudsley but at Italia. Yes.
 S.F. In Italy, not in Camberwell, south London where it's well known to be located?
 G.O. No, I would say that this part is the first cousin of the original.
 S.F. Similar or quite different?
 G.O. From what I understand I would say that it is nowhere near as modern as its true English equivalent. But let me say that I have been very impressed with what I have seen here and I would suggest that the British National Health Service would be well advised to send foraging and investigative teams to Italy proper, including this building, to ask questions and to observe them carrying out their duties.

Hallucinatory experiences may be troublesome; visual hallucinations are most evident, perhaps because they can often be inferred from the patient's behaviour, for example as they are seen to pluck at imaginary objects on their bedlinen.

Weston and Whitlock (1971) describe an example in which delusions apparently stemmed from a vivid hallucinatory experience occurring as part of the early post-traumatic delirium. The patient related an episode in which he believed he saw his parents being shot by Chinese communists. Thereafter when his family visited him he believed them to be impostors who had assumed their exact appearance in order to trick him. The profound memory disturbance from which the patient was suffering at the time had prevented him from realising that the head injury had occurred, or from reintegrating his vivid fantasy into normal daily experience.

These early psychotic states with confabulations, delusions and hallucinations are almost certainly a result of the generalised disturbance of brain function. They usually

remit spontaneously, although once recovery has taken place amobarbital may produce a return of symptoms (Weinstein & Kahn 1951).

Post-traumatic agitation

During the post-traumatic delirium some patients pass through an excitable and overactive phase with florid disturbance of behaviour that can pose serious problems of management. Sometimes this is attributable to the abnormal experiences and delusional misinterpretations of a post-traumatic delirium, but sometimes it proves to foreshadow enduring changes of temperament and behaviour occasioned by the injury. The patient may be abusive, aggressive, sexually disinhibited and markedly uncooperative. This phase of agitated behaviour occurs in about 10% of patients with severe brain injury (Brooke *et al.* 1992). For most patients it will only last a few days and for the vast majority the agitation resolves spontaneously within a few weeks. Sexually disinhibited behaviour, when present, often follows the same pattern of recovery. Agitation almost invariably disappears before resolution of PTA. This is consistent with the observation that agitation and attentional deficits tend to go hand in hand (Corrigan *et al.* 1992). Agitated behaviour is

associated with frontotemporal injury and doubles the risk of later emotional sequelae (van der Naalt *et al.* 2000). In some patients with post-traumatic agitation, for example following orbitofrontal injury (Silver & Yablon 1996), the constant pacing resembles akathisia seen in patients on antipsychotic drugs.

Post-traumatic amnesia

The period of PTA, which includes the period of unconsciousness and post-traumatic delirium when these are present, may be defined as the amnesic gap from the moment of injury to the time of resumption of normal continuous memory. It ends at the time from which the patient can later give a clear and consecutive account of what was happening around him.

Towards the end of PTA there may be a period when outward behaviour appears to have returned to normal, so that observers are easily misled into thinking that full recovery has occurred, but which the patient subsequently fails to recollect. During this period some degree of temporal disorientation is almost always in evidence if opportunities arise to test for it with care, but even questions designed to test short-term memory may sometimes be answered adequately. Memory functions may have recovered but not yet enough to lay down a permanent record. It is only when this period ends that the patient has recovered from their PTA. Some would argue that it is therefore only in retrospect that the true duration of PTA can be determined with certainty.

With milder injuries there may be no significant post-traumatic delirium; on recovery of consciousness the patient becomes alert and orientated. However, in some of these patients for a time events fail to be recorded in memory and the injury is therefore followed by an amnesic gap. PTA may even be seen in those without loss of consciousness. The classic example is that of the schoolboy struck during a game of football but not rendered unconscious. He may then continue to play, but later proves to have no recollection of the part of the game which immediately followed the injury. Similar examples are sometimes seen in boxers. Usually performance is noted to be substandard during the continuation of activity.

Occasionally some brief isolated experiences, islets of memory, are recalled immediately after the injury, usually in an inaccurate and confused way, and thereafter the dense amnesic period begins.

A boy of 18 skidded in a car and hit a telegraph pole, sustaining a fractured skull and broken leg. He clearly recalled switching off the engine and forcing open the jammed car door, both of which were subsequently corroborated. Thereafter he could recall nothing until he came round in hospital some 48 hours later (Whitty & Zangwill 1966).

A more delayed onset to the amnesic phase may of course be seen when complications such as extradural haemorrhage lead to a second period of unconsciousness after full recovery has been attained; here events may be recalled from the lucid interval preceding the haemorrhage, and this may be of several hours' duration.

Patients are described as 'being in PTA' as a convenient shorthand to describe the acute recovery period from recovery of consciousness until the end of PTA. During this period patients gradually emerge from a state of impaired consciousness to a period where they are disorientated and amnesic but alert, with the whole episode ending, often gradually, as continuous day-to-day memory is achieved. Impairments of attention, orientation, memory and psychomotor speed are to be found throughout this period. There is no evidence that attentional problems are confined to a distinct confusional state (delirium) within the amnesic gap. There is therefore an argument for describing the whole of PTA, once consciousness is regained, as a post-traumatic confusional state.

There have been several detailed studies of patients during the course of the PTA. Levin and colleagues have made a number of interesting observations. Tests of remote memory have revealed a marked temporal gradient (Levin *et al.* 1985). Events from primary school days were, for example, better remembered than events from young adult life. The same technique applied to patients after resolution of PTA showed no such gradient, but demonstrated equivalent levels of recall for all life periods. A study of orientation during PTA showed that the usual sequence of recovery was for person, then place, then time (Levin 1990). The date was characteristically displaced backwards, for up to 5 years in severe injuries, then the discrepancy diminished as orientation improved.

Ewert *et al.* (1989) made an interesting comparison between procedural and declarative (episodic) memory during the course of PTA. Patients can acquire and retain new skills (mirror reading, maze learning and a pursuit-rotor task) during the PTA, while remaining disorientated and amnesic for ongoing events. Stuss *et al.* (1999) found gradual recovery of attention (e.g. months backwards), memory (e.g. recalling three words after 24 hours), and orientation, with easier tasks recovering before more demanding and effortful tasks. There was considerable overlap in the timing of recovery, but in general with attention recovering before memory. Wilson *et al.* (1999) also observed a gradual recovery of function; across a battery of neuropsychological tests of memory and attention there was no evidence of any sudden improvement across all tests as PTA ended, and the pattern of recovery was different for one patient compared with another. Slowing of reaction time and speed of information processing was prominent. This slowing was found to distinguish patients in PTA from those with a long-term amnesic syndrome (Wilson, B.A. *et al.* 1992).

Of interest is the relationship between recovery of orientation to time, person and place, and recovery of memory, as measured by the ability to remember items after a 24-hour delay. Gronwall and Wrightson (1980) showed that many patients are orientated but still show memory problems, an observation supported by Stuss *et al.* (1999) who showed, on average, orientation recovering before memory. However, Tate *et al.* (2000) suggested that the pattern they

observed, with amnesia resolving before disorientation in 94% of cases, was because they had only studied patients with severe TBI.

In many, the termination of PTA is abrupt. The amnesic phase may have lasted from several minutes to several weeks, yet finally ends sharply with the return of normal continuous memory. It is for this reason that many patients can retrospectively give a firm end-point to their PTA. However, in others brief islands of memory at first emerge, vaguely recalled and jumbled in temporal sequence, before the continuity of memory is gradually restored. In those very severe injuries where enduring memory difficulties are to supervene, it is not possible to define the end of PTA.

False memories

The confabulatory state, often with delusional disorientation, that is found during PTA has been described above. Patients are usually subsequently found to be amnesic for the period and have no recollection of their psychotic experiences.

Occasionally the circumstances of the injury are recalled in a confused and muddled manner. This can have important medicolegal repercussions. Russell (1935) reported a patient who had a motorcycle accident and subsequently ascribed his injuries to an attack by the dog which had caused it. He later elaborated this by maintaining that the dog's owner had attacked him directly. In this case the delusions were short-lived and cleared as the post-traumatic confusion receded. A similar case was cited in which a doctor took home a boy who had fallen off his bicycle and was later accused by the boy of having run him down.

False memories, which at first sight are convincing enough, have sometimes been found to centre on a previous injury.

A dispatch rider was concussed in a motorcycle accident. Following a period of complete unconsciousness he was confused and drowsy for 2–3 days, and after treatment at a local hospital was transferred to a special head injury unit 10 days later. When seen at that time he gave details of the accident, including its locale and the incident leading up to it, and recounted his journey from the first hospital. He gave his name and army number correctly, but persistently underestimated his age by 2 years. At clinical examination he appeared to be rational and fully orientated. It finally transpired, however, that he was giving details of an accident he had had before joining the army some 2 years previously, and that the description of his journey to the second hospital was also a false reminiscence. His final PTA was assessed as 12 days. It involved the period of false reminiscence and the first 2 days of his stay in the second hospital (Whitty & Zangwill 1966).

Some patients, when describing their memories of the trauma months or years later, will admit that they are uncertain how much of what they remember is in fact their own recollection of what they experienced and encoded at the time, and how much is in fact a reconstruction based on what they have been told of what happened. Harvey and Bryant (2001) reported that 40% of patients with mild TBI who early on had no recollection of the trauma, when asked 2 years later remembered the accident. How much of this recovery of memory was due to shrinkage of RA due to improved recall processing, and how much was in fact a reconstruction, is uncertain.

Retrograde amnesia

The duration of RA is measured as the time between the moment of injury and the last clear memory from before the injury which the patient can recall. The patient can often indicate with fair precision the last event which he can clearly recollect.

The RA is usually dense, even for events of high emotional significance and of course involving details of the accident itself. Usually the RA is much shorter than the PTA (Russell & Nathan 1946), although in rare exceptions the reverse is seen. Long retrograde gaps are generally seen only with more severe injuries, and these may be of many days' or weeks' duration. Conversely, examples of mild injury are seen in which no RA occurs whatever, and full details of the injury can be recalled up to the moment of loss of consciousness.

The organic basis for very long RA has come under suspicion, and certainly prolonged RA following mild head injury has often proved to be psychogenic in origin with, for example, functional imaging with SPECT being entirely normal (Di Renzi *et al.* 1997). Here the emotional shock of the accident is principally to be blamed. Nevertheless, long RA may be seen with other forms of organic brain damage, and experienced observers have agreed that after severe head injury a long RA may sometimes be directly attributable to organic factors. For example, Symonds (1962) reported a permanent RA of 1 year for which there was no indication other than that organic factors were at work. Russell and Nathan (1946) investigated the effect of thiopental narcosis on the duration of amnesias, and found a reduction in only 12 of 40 cases investigated. The reductions were mostly trivial in amount, and did not include material likely to have been repressed by psychological mechanisms. Moreover, the recovered material always bordered the fringes of the amnesic gap, suggesting again that it was substantially organic in origin. More recently, hypoactivation of an area of the right frontal lobe involved in episodic memory retrieval has been described in a patient with a prolonged RA (Levine *et al.* 1998), whereas another showed bilateral reduction in ^{18}F -FDG metabolism in anterior cingulate cortex and hippocampus (Mattioli *et al.* 1996).

The RA as determined shortly after injury may prove to be misleading. At first it may be very long, then shrink in the days or weeks that follow as normal orientation is regained. The final estimate should therefore not be made until the patient has emerged from the period of PTA and the fullest possible recovery of cerebral function has occurred.

Measuring head injury severity

Clinical methods

Perhaps the first stage in the neuropsychiatric assessment of a patient with a head injury is to determine the severity of the injury to the brain (Box 4.1). There are three useful clinical measures of head injury severity as predictors of long-term outcome: the GCS measured in the immediate or early aftermath of the injury, the duration of loss of consciousness, and the duration of PTA. In addition it is necessary to consider whether the injury has resulted in any neurological symptoms and signs, e.g. pupillary changes, or a hemiparesis, or alteration of behaviour in the immediate aftermath suggestive of a delirium, or whether there has been a skull fracture or other findings on neuroimaging. Although abnormalities on EEG correlate with injury severity, such findings are rarely used as part of the neuropsychiatric assessment to determine injury severity. The period of RA, i.e. the period leading up to the injury for which memories have been lost, does not correlate very well with injury severity.

Marshall *et al.* (1991) proposed that findings of diffuse injury on early CT brain imaging could contribute to head

injury classification, particularly for those who on clinical measures seemed at low risk but where the CT scan showed brain injury. However, their method does not rate the presence or absence of subarachnoid haemorrhage, an important determinant of injury severity. A simple grading of CT scans, which includes whether subarachnoid haemorrhage is present, may do better as a predictor of outcome (Wardlaw *et al.* 2002).

Glasgow Coma Scale

The GCS (Teasdale & Jennett 1974) is routinely used in the management of acutely head-injured patients. The patient's clinical state is charted regularly on three graded parameters: motor responsiveness (no response, extensor response to pain, flexor response, withdrawal response, localising response, obeying commands), verbal performance (nil, without recognisable words, no sustained exchange possible, confused conversation, orientated for person, place and time) and eye opening (nil, in response to pain, in response to speech, spontaneously). Numerical scores are summated for the best responses obtained under each category at a defined point in time. In this way useful predictions can be made, often within 24 hours of injury.

Given that in any one patient serial ratings are usually taken, there is uncertainty about the timing of the recording that should be used as the best measure of injury severity. Some recommend the score on arrival in the emergency room, but if this is to be valuable as a measure to compare one patient with another, or one cohort with another, it does depend on the injury to hospital interval being reasonably consistent; in the UK this is usually about 30–60 minutes. The WHO Task Force (see below and Box 4.2) recommend using

Box 4.1 Indicators of head injury severity

- Depth of unconsciousness as assessed by GCS in the immediate aftermath of the injury. A score of 3 indicates absent responses, i.e. deep coma; 15 is normal conscious level
- Duration of loss of consciousness/coma
- Evidence of behavioural/cognitive change in the immediate aftermath suggestive of delirium
- Neurological symptoms and signs
- Evidence of skull fracture and/or other abnormalities on neuroimaging
- Blood in the CSF
- Duration of PTA: interval between the injury and return of normal day-to-day memories

Less useful indicators

- Duration of RA: the period leading up to the injury for which memories have been lost
- Abnormalities on EEG
- Markers of cell damage (e.g. S-100B)
- Evidence of injury to head, e.g. lacerations, bruising, bleeding from ears, fracture of maxilla/zygoma

Box 4.2 Definition of mild traumatic brain injury recommended by the WHO Collaborating Task Force (Carroll *et al.* 2004a,b)

Mild traumatic brain injury is an acute brain injury resulting from mechanical energy to the head from external physical forces. Operational criteria for clinical identification include the following.

- One or more of: confusion or disorientation, loss of consciousness for 30 minutes or less, PTA for less than 24 hours, or other transient neurological abnormalities such as focal signs, seizure, and intracranial lesion not requiring surgery.
- GCS score of 13–15 at 30 minutes after injury or later on presentation to hospital.

These manifestations of mild traumatic brain injury must not be due to drugs, alcohol or medications, caused by other injuries or treatment for other injuries, caused by other problems (e.g. psychological trauma, language barriers or coexisting medical conditions), or caused by penetrating craniocerebral injury.

the score at 30 minutes, or at the first opportunity after this. Others suggest that the worst GCS score should be used (Levin *et al.* 1990b) (see below). If the patient is sedated and ventilated, the GCS rating must have been taken before any sedation is offered. It may not matter which single measure of GCS is used, initial or lowest, since both have about the same, rather poor, ability to predict outcome (Zafonte *et al.* 1996). Katz and Alexander (1994), studying a cohort of very severely injured patients (the great majority had PTA greater than 1 week), used the highest (most responsive/alert) GCS score in the first few hours after injury, arguing that this was the best indication of the severity of diffuse injury, and was less vulnerable to the effects of focal injury or medication or very early effects before cardiopulmonary resuscitation. Using the highest early score is only applicable to those with very severe injury and has generally not been adopted.

Duration of loss of consciousness

It should come as no surprise to find that the duration of loss of consciousness following a closed head injury is a good marker of injury severity. However, in the very mild injury severity range, for example concussion in sport, whether or not someone has lost consciousness may not be critical. Loss of consciousness is often absent in concussive injuries in sport, and when present rarely lasts longer than 5 minutes. In this setting it has been difficult to demonstrate that those who sustain loss of consciousness do worse than those with no loss of consciousness in terms of reduced speed of information processing over the days following the head injury (see Mild TBI, Loss of consciousness and outcome, later in chapter). However, when it comes to comparing those who have sustained very brief loss of consciousness with those with prolonged loss of consciousness, then quite strong correlations between duration of loss of consciousness and outcome are found (Asikainen *et al.* 1998). Where serial GCS scores have been measured, the end of loss of consciousness is best defined by time to follow commands, i.e. the time when the patient scores 6 on the motor scale ('responds to commands') (Temkin *et al.* 1995; Whyte *et al.* 2001). A total GCS score of 9 or below usually indicates unconsciousness.

Duration of post-traumatic amnesia

The importance of the duration of amnesia as a guide to the severity of injury and prognosis for recovery was first clearly shown by Russell (1932). The duration of PTA shows close correlations with objective evidence of damage to brain tissue, as reflected in neurological residua such as motor disorder, dysphasia or anosmia, or enduring defects of memory and calculation (Russell & Smith 1961; Smith 1961). Moreover, the PTA is a permanent index of severity, and available to the clinician who enquires long after the injury. Measurement of PTA has now become a well-attested part of clinical practice, hence the importance of striving to record in every case the precise details of the post-traumatic gaps in memory.

The early descriptions of the use of PTA as a measure of injury severity suggest that it be used as a retrospective measure (Russell & Nathan 1946); the patient is asked what he or she remembers of events in the post-injury period and in this way the time until the return of continuous day-to-day memories can be determined. Subsequently, it has been argued that a more reliable estimate of PTA duration, only relevant to those with severe injuries, requires prospective assessment. Once the patient is conscious, regular testing enables the clinician to determine when he or she is reliably able to lay down memories from one day to the next (Shores *et al.* 1986). The end of PTA is usually defined by three consecutive days of perfect scores on simple memory tests, although there is ongoing debate about the best criterion to use (Tate *et al.* 2006). This debate rests heavily on the premise that PTA has an objective end-point. Some would argue that there is little consistency in the pattern of recovery of PTA, which consists of gradual recovery of different domains of memory and orientation at different times (see discussion above). Therefore as one makes the task or criterion used to define the end of PTA more difficult, the measured PTA duration will be longer; what criterion is set is somewhat arbitrary. Despite such complexities, good agreement between retrospective and prospective assessments of the duration of PTA are to be found (McMillan *et al.* 1996). This is useful clinically. In the absence of prospective measures of PTA it is still possible in the clinic, months or years after the injury, to assess the duration of PTA and use this as a measure of injury severity.

Classifying head injury severity

Despite the uncertainty about when to measure the GCS score for grading injury severity (see above), there is more consistent standardisation of head injury classification based on GCS than for either of the other two measures (Carroll *et al.* 2004a). It is now generally accepted that a GCS score of 13–15 defines mild TBI, 9–12 moderate brain injury, and 8 or less severe brain injury. Some define very severe as a GCS score of less than 6 (Table 4.2) while others state that those with a GCS score of 13 are more like those with a score of 12 than those with a score of 14/15, and that therefore it may be better to restrict mild TBI to GCS scores 14 and 15.

There is little consistency in the classification of head injury severity using loss of consciousness. It has been suggested that thresholds for minor, moderate, severe and very severe injury should be 15 minutes or less, more than 15 minutes but less than 6 hours, between 6 and 48 hours, and greater than 48 hours, respectively (Medical Disability Society 1988).

Russell and Smith (1961) proposed a classification of head injury severity according to duration of PTA: PTA <1 hour, slight concussion; PTA 1–24 hours, moderate concussion; PTA 1–7 days, severe concussion; PTA >7 days, very severe concussion. Jennett and Teasdale (1981) extended the range

Table 4.2 Proposed classification of severity of traumatic brain injury.*

	Mild	Moderate [†]	Severe	Very severe [‡]
GCS	13–15	9–12	6–8	3–5
LoC	≤30 min	>30 min to 6 hours	>6 hours to 7 days	>7 days
PTA	≤24 hours	>24 hours to 14 days	>14 days to 8 weeks	>8 weeks

* The correspondence for the three measures, GCS (Glasgow Coma Scale), LoC (loss of consciousness) and PTA (post-traumatic amnesia), in terms of injury severity is based on data from Asikainen *et al.* (1998). Note that for any given LoC the length of PTA, on average, increases with age. For patients over 40, compared with those less than 40, the PTA is likely to be about 50% longer for any given LoC.

[†] Given that a GCS score >10 is usually associated with recovery of consciousness and that GCS is measured on arrival in the emergency room, which is usually within 1 hour of injury, the criteria for GCS and LoC will not always match. With regard to the threshold between moderate and severe injury, Bishara *et al.* (1992) found that about 50% of those with PTA duration of 1–4 weeks had GCS score 6–8 while the rest had GCS score of 9 and above, suggesting that the GCS threshold 8/9 is about equivalent to PTA threshold of 2 weeks. Stuss *et al.* (1999) suggested the best cut-off between moderate and severe to be a PTA of 16 days. An alternative classification according to PTA duration might be: moderate, >24 hours to 1 week; severe, >1 week to 4 weeks; very severe, >4 weeks.

[‡] GCS score 3–5 is commonly used as a category of very severe within the severe range. The equivalence of LoC >7 days to PTA >8 weeks is based on Katz and Alexander (1994). Bishara *et al.* (1992) found that all those with GCS score 3–8 had PTA >4 weeks while about half of those with PTA >4 weeks had GCS score 6–8; this is compatible with a threshold of GCS 5/6 as being equivalent to PTA of 8 weeks.

by defining very severe injury as PTA of 8–28 days and extremely severe injury as PTA >28 days. Two subsequent studies demonstrated the value of extending the classification to PTA durations greater than 7 days; van Zomeren and van den Burg (1985) found that those with PTAs of greater than 2 weeks had markedly higher rates of failure to return to work than those with PTAs of less than 2 weeks, and Bishara *et al.* (1992) found that those with a PTA of less than 8 weeks were quite likely to do well, whereas if the PTA was greater than 8 weeks a poor outcome with considerable disability was likely.

Carroll *et al.* (2004a) reviewed the various criteria that have been used in different studies to define mild TBI, in other words the boundary between mild and moderate injury. The criteria for loss of consciousness ranged from less than 5 to less than 30 minutes, and for PTA studies tended to use either less than 1 hour or less than 24 hours as the criterion. For GCS there was much greater consistency, with the majority using GCS scores of 13–15 to define mild TBI. Based on this review the WHO Task Force recommended that mild TBI be defined by a GCS score of 13–15, loss of consciousness of less than 30 minutes, and PTA of less than 24 hours (see Box 4.2), although it was noted that these criteria were not necessarily congruent, i.e. a patient might have a GCS score of 13 but a PTA of a few days. However, for the boundary between moderate to severe injury there is no consensus as to what combination of GCS, loss of consciousness and PTA duration to use.

Given the lack of evidence for any stepwise changes in the effect of increasing injury severity on outcome, the decision as to what thresholds to use to classify injuries as mild, moderate or severe is essentially arbitrary. What is required is a classification that ensures the best internal consistency of the three measures, GCS, loss of consciousness and PTA. Empirical data on the equivalence of these three measures is needed to determine the most internally consistent thresholds. For example, Katz and Alexander (1994) demonstrated that in severe diffuse traumatic injury the best fit between a patient's loss of consciousness and PTA was defined by the following equation:

$$\text{PTA (weeks)} = 0.4 \times \text{LOC (days)} + 3.6$$

where LOC is loss of consciousness. Norrman and Svahn (1961) obtained very similar results in an unselected series of 24 cases of severe head injury with loss of consciousness greater than 1 week. PTA duration was predicted by the equation:

$$\text{PTA (weeks)} = 0.44 \times \text{LOC (days)} + 0.2$$

correlation coefficient $r = 0.69$

This tallies with clinical experience; on average the duration of PTA is several times longer than the duration of loss of consciousness. This relationship is perhaps most consistent for diffuse injuries. Katz and Alexander (1994) found that in patients with focal injuries it was more difficult to

demonstrate correlations between PTA and loss of consciousness. Those with relatively long PTA durations compared with loss of consciousness may have more extensive damage to the cerebral hemispheres compared with central brain areas (Wilson *et al.* 1994).

The data from Asikainen *et al.*'s (1998) study looking at predictors of outcome may be used to inform the selection of thresholds for the three measures. Using their data on the rates of good outcome according to severity in a large cohort, then the outcome of patients defined by a GCS score, on admission to hospital, of 13–15 (mild injury; about two-thirds good outcome) matches quite well with those with loss of consciousness less than 30 minutes and PTA duration less than 24 hours. Those with GCS scores of 9–12 (moderate injury; about 28% good outcome) have very similar outcomes to those with loss of consciousness between 30 minutes and 6 hours and PTA durations between 24 hours and 14 days. Finally, the generally poor outcome of those with GCS scores of 8 or less (severe injury; only about 10% good outcome) tallied with the outcome of all those with loss of consciousness of 6 hours or more or with PTA of 14 days or more. The criteria of Table 4.2 are based on these data.

Predicting outcome based on measures of head injury severity

On the neurosurgical unit for patients with very severe injury, the GCS score, often in combination with pupillary signs and measures of raised intracranial pressure, helps to predict whether somebody is likely to survive the first year, and if so with severe disability or with reasonable recovery (Levin *et al.* 1990b; Signorini *et al.* 1999b). However, changes in neurosurgical practice over recent years, for example greater use of early elective ventilation and sedation, may mean that the GCS score has lost its predictive power in this situation (Balestreri *et al.* 2004).

GCS scores are generally not as good as loss of consciousness or PTA at predicting who is likely to achieve good recovery and who is likely to be left with significant disability (Bishara *et al.* 1992; Katz & Alexander 1994). Asikainen *et al.* (1998) did get reasonable correlations of functional outcome with GCS, but loss of consciousness and PTA were better at predicting the important outcome of return to work.

There is some uncertainty as to whether loss of consciousness or PTA is better at predicting longer-term outcome. One would expect loss of consciousness, being more proximal to the trauma, to be a better marker of the severity of the impact and the damage sustained. PTA is more likely to be responsive to the effects of early interventions; neurosurgeons may even use it as a surrogate outcome measure (Ellenberg *et al.* 1996). One advantage that PTA may have over loss of consciousness when used to predict longer-term outcome is that PTA is at least partly due to executive and memory impairments, and it is these impairments that are important determinants of outcome. There may also be commonality between those systems, particularly involving frontal and temporal lobes, that if damaged contribute to prolonged PTA and those which result in behavioural changes that will disadvantage a person in the workforce. Psychiatric disablement shows an important relationship to the duration of PTA, particularly where organic mental disabilities such as intellectual impairment, euphoria,

disinhibition or aspects of 'frontal lobe syndrome' are concerned (Lishman 1968). In Steadman and Graham's (1970) series the mean duration of PTA was significantly increased in patients who showed post-traumatic change of personality. These changes handicap a person's employability.

Reasonably high correlations between PTA duration and likelihood of return to work have been found ($r = 0.54$) in patients with severe injury (van Zomeren & van den Burg 1985). However, in head-to-head comparisons it has been difficult to demonstrate that PTA is a better predictor of outcome than is loss of consciousness (Asikainen *et al.* 1998).

In the individual patient clinical common sense is needed to interpret the head injury severity measures. For any given GCS, loss of consciousness or PTA, various factors if present will result in overestimation of injury severity. These include alcohol or drug intoxication at the time of injury, eye swelling, ventilation and sedation and other prescribed drugs, particularly analgesics. Malingering should occasionally be considered, for example if there is a surprisingly long PTA compared with other injury severity measures. In patients who develop a persistent anterograde amnesia, the PTA duration will be prolonged indefinitely and is no longer particularly valuable as an injury severity measure.

Injury severity measures are fairly weak predictors of outcome. At best they are perhaps able to explain 50% of the variance in outcome at 1–2 years. The wise clinician will be wary of offering firm predictions of outcome, particularly in the early post-injury period. They will have seen patients who, despite having suffered a PTA of many weeks, successfully return to intellectually demanding work. Yet others, without any suggestion of pre-injury vulnerability or concerns about compensation that might complicate recovery, do badly despite clinically trivial injury. Bearing these caveats in mind, Table 4.3 provides a rough guide to the likely

Table 4.3 Likely outcome for given duration of PTA.*

PTA duration	Likely outcome
<1 hour	Usually return to work within 1 month
<1 day	Usually return to work within 2 months
<1 week	Usually return to work within 4 months
>1 week	Often followed by invalidism extending over the greater part of a year
>2 weeks	Almost inevitable measurable residual cognitive problems, of variable impact
>1 month	At best a reduced work capacity, at worst some community supervision
>3 months	Makes voluntary or subsidised work a likely best outcome, while at worst residential placement may be needed

* This summary is based on the data and estimates of Steadman and Graham (1970) and on Greenwood (2002). Note that as age increases, poor outcome is more likely.

outcomes of patients; when interpreting these results it is important to remember the vital contribution of age to outcome. Predictions of prognosis may be helped using other measures. For example, measures of early cognitive status on emergence from PTA help predict outcome even after taking PTA duration into account (Sherer *et al.* 2002).

As sophisticated pathway analysis has combined measures of pre-injury status, for example age and drug abuse, with injury severity and status at 6 months after injury to predict outcome at 1 year in patients with severe injury (Novack *et al.* 2001). Once cognitive status at 6 months had been taken into account, head injury severity had little predictive power, suggesting that much of the effect of head injury severity on outcome (e.g. community integration and employment at 1 year) is effected through cognitive impairments. Emotional status at 6 months, measured with the Neurobehavioural Rating Scale, did not correlate with outcome at 1 year, yet premorbid status did. Although this analysis helps us understand the pathways underlying the multivariate contributions to outcome, its complexity militates against it being taken up as a clinically useful tool.

An important, though not overriding qualification to the above concerns the situation in open as opposed to closed head injuries. In penetrating injuries, particularly those due to high-velocity missiles, there is a tendency for the PTA to be very short or even absent in up to 50% of cases (Russell 1951). Nevertheless, even among penetrating head injuries a close relationship exists between the length of PTA and the amount of psychiatric disability or intellectual impairment as assessed in general terms 1–5 years later (Lishman 1968).

Chronic sequelae of head injury

With recovery from the acute stages, a mild head injury is quite compatible with return to full efficiency, both physically and mentally. This important fact is not always appreciated by the patient and his relatives for whom the very term 'concussion' can have ominous overtones. Nevertheless, head injury does account for a great deal of chronic disability. Common physical defects include cranial nerve lesions such as anosmia, oculomotor pareses, visual field defects and motor disorders resulting from cortical or brainstem lesions. Slurred speech, ataxia and paresis of the limbs are the common physical sequelae. Peripheral sensory defects are seen less frequently. In penetrating injuries, or after complications due to intracranial bleeding, such focal neurological defects will be more common. Generally the recovery of the physical sequelae tends to reach a plateau by 1 or 2 years after injury, although there are reports of for example hemiplegia improving over many years. Dysphasia is particularly likely to improve in the long term (Thomsen 1984).

The clinical importance of the mental aftermaths cannot be overstressed. Observers are uniformly agreed that problems such as cognitive incapacity or change of personality far out-

strip the physical sequelae as obstacles to rehabilitation and as a source of long-term disability (Bond 1976; Field 1976; Jennett *et al.* 1981). Decline in employment is more likely to be associated with mental than physical factors (Roberts 1976; Brooks, D.N. *et al.* 1987), likewise the strain imposed on families and those responsible for care (McKinlay *et al.* 1981; Thomsen 1984; Florian *et al.* 1989).

Recovery and long-term outcome

Several studies have attempted to chart the pattern and speed of recovery in patients followed prospectively. All agree that the major gains are usually made during the first post-injury year, the most substantial improvement occurring in the first 6 months. The Glasgow workers (Bond & Brooks 1976; Jennett *et al.* 1977, 1981) have used broad categories of social outcome rather than focusing on cognitive defects alone; using the Glasgow Outcome Score, patients were classified in terms of remaining dependent on daily support, being able to travel and work in sheltered environments, or resuming normal life even in the face of minor continuing deficits (Jennett & Bond 1975). They found that only a minority of severely injured patients changed from one major grade of social outcome to another after the first post-injury year. However, more recent studies suggest a less certain future for the patient. Some have found that during subsequent years continuing improvement can be encountered to an extent that would probably not have been predicted. Others have found that a significant proportion of patients may in fact deteriorate compared with how they were in the early months after injury (see below).

Psychometric testing has shown that different components of cognitive function tend to plateau at different periods. Thus Mandleberg and Brooks (1975) found that scores on verbal subtests of the Wechsler Adult Intelligence Scale (WAIS) tended to approach those of a non-injured control group after 1 year, whereas recovery on performance subtests continued for about 3 years. The slower restitution on performance items no doubt depends on their complex nature, requiring a synthesis of numerous capacities such as perception, attention, learning and psychomotor speed. The recovery of memory functions has been investigated similarly (Brooks 1976; Parker & Serrats 1976), again with indications that most of the improvement takes place during the first year.

However, even over the first year or two of recovery there may be quite different patterns of recovery. Two studies have shown that in a proportion of patients, early improvement in the first 6 months may be followed by a deterioration in memory (Ruff *et al.* 1991) or behaviour (Dunlop *et al.* 1991) within 12 months. Depression, alcohol and social factors predicted who was likely to deteriorate over the 6–12 months after injury; this scenario may be similar to the post-concussion syndrome (see below).

Therefore in all but the mildest cases a firm prognosis should not be attempted until 2 or 3 years have elapsed from the time of injury. And even after this there may be improvement in social functioning probably due to adaptation and adjustment to the deficits which persist. For example, Thomsen (1984) found that half the patients who could not be left alone at 2.5 years were living independently when followed up 10–15 years later. She suggested that improvement in psychosocial functioning can continue for many years. Wilson (1994, 1995) found that 8 of 25 patients with head injury that she had seen for memory rehabilitation 5–12 years before had improved.

Corkin *et al.*'s (1989) study of soldiers surviving penetrating head injury in the Second World War suggested a less optimistic outcome in the long term, possibly due to accelerated decline with ageing in consequence of depleted neuronal reserves.

Corkin *et al.* (1989) traced 50 or so soldiers who had had penetrating head injuries and compared them with 27 controls who had suffered peripheral nerve injuries. The groups were matched for age, education and premorbid intelligence. All subjects had already undergone extensive neuropsychological investigation 30 years earlier, and changes in performance on these same tests could now be accurately assessed. Head injury had led to accelerated decline on total scores from the Army General Classification Test (AGCT), and on its arithmetic subtest, when head-injured and non-head-injured subjects were compared. Means were in the same direction for the vocabulary and the block-counting subscales, and on a hidden figures test. Exacerbated decline was greatest among older subjects, and was common rather than restricted to a small subsample, affecting for example some 75% of persons where the AGCT total scores were concerned. The head-injured patients were not demented, and Corkin *et al.* made the important clinical point that before diagnosing dementia in a patient with a history of head trauma, one should consider the possibility that exacerbated cognitive decline is the responsible factor rather than a new pathological process.

These findings from detailed psychometry support the impressionistic report from Walker and Blumer (1989) that mental deterioration appeared to affect one-quarter of the head-injured soldiers they followed up after the Second World War, starting at around 25 years after injury; they had all suffered from post-traumatic epilepsy. The changes, often not recognised by the subjects themselves but apparent to their wives and friends, took the form of forgetfulness, inattention, mental fatigue and confusion. The tendency to deteriorate did not correlate with the persistence of any type of seizure. In contrast to these findings, Newcombe (1996) has been unable to find evidence of accelerated cognitive decline from her extensive survey of British soldiers sustaining focal brain injuries in the Second World War.

Recent studies of closed head injury, in civilian cohorts, also point to the risk that a proportion of survivors of head injury will deteriorate over time. Perhaps the first indication of this came from Glasgow (Brooks *et al.* 1986), where com-

parison of relatives' reports at 1 year with their reports at 5 years after injury found that many were reporting greater problems at 5 years, for example disturbed behaviour and threats of violence. In Australia a study comparing patient reports at 2 years with 5 years after injury was a little more optimistic (Olver *et al.* 1996), with improvements in some ratings. However, this optimism was qualified by the observation that there was an increase over the 3-year interval in the number out of work. In the USA a study based on a database of several rehabilitation centres has examined outcome measures collected longitudinally up to 5 years after injury (Hammond *et al.* 2004). As expected the majority of patients (75%), comparing their status at 1 year after injury with that at 5 years, were unchanged. Of those who changed by more than one point on the Disability Rating Scale, twice as many improved (18%) as deteriorated (7%). However, when Millar *et al.* (2003) compared outcome, measured using the Glasgow Outcome Score, at 6 months after injury with that on average almost 18 years later, they found twice as many had deteriorated (32%) as improved (15%). The deterioration was not predicted by ApoE $\epsilon 4$ status. Whitnall *et al.* (2006) recruited patients from several general hospitals with a broad range of severity but with mild injury comprising the majority. Scores on the Glasgow Outcome Score at 1 year after injury were compared with those about 5 years later. As many patients had deteriorated (rated 'good recovery' at 1 year but 'disabled' at 5 years) (12%) as had improved (13%). Of particular interest to the neuropsychiatrist was the observation that at 5–7 years those who deteriorated, compared with those who improved, were more depressed and anxious, had lower self-esteem and had more problems with alcohol.

Himanen *et al.* (2006) did find evidence of long-term decline. They followed up patients on average 30 years after their initial assessment, which was typically about 2.5 years after injury. Over half were severe head injuries and the mean age at follow-up was 60. A pattern of slight general decline was seen, particularly in men and tending to involve visuospatial functioning and visual memory. Younger patients tended to be spared and more severely affected patients showed greater decline on some tests. On a general measure of mild deterioration, 56% did worse while 23% did better at 30-year follow-up.

It is perhaps of interest that of these studies, those with the better long-term outcome (Thomsen 1984; Wilson 1994, 1995; Hammond *et al.* 2004) tended to come from follow-up of patients who had been through rehabilitation. This may be an ascertainment effect; only those likely to do well in the long term turn up for rehabilitation in the first place. However, perhaps early rehabilitation does place the patient and carers in a better position to cope, over the longer term, with the sequelae of head injury.

When interpreting long-term follow-up studies it is important to remember that in general the rates of follow-up are quite low, with only a few studies achieving better than 50%

follow-up. Those with less education, those who are more socially deprived or from ethnic minorities, those who acquire the injury because of violence, or those who have a history of alcohol or drug abuse are less likely to be followed up (Sullivan & Corkin 1984; Corrigan *et al.* 2003). So it is likely that studies with low follow-up rates are going to report better outcome than those that have been able to achieve a more comprehensive evaluation at follow-up.

Finally, it is worth noting that these long-term studies consistently find high levels of mortality. Accidents, alcohol and suicide contribute to the late mortality after head injury (Pentland *et al.* 2005), particularly in those with mild injury.

Head injury as a risk for dementia

Roberts (1976, 1979) focused particular attention on the question of late dementia in his follow-up of 291 survivors from very severe injuries. Careful enquiry 10–25 years later yielded evidence of worsening in 31 patients, and in 10 the possibility was raised of a progressive dementia. However, taking all associated factors into account, such as age, alcoholism, epilepsy and hydrocephalus, there was little to support the notion that a single head injury could set in train a progressive dementing process. Some patients may have had Alzheimer's disease unrelated to the injury, but a more general explanation seemed to lie with the natural processes of ageing affecting a brain already depleted of its functional reserves. Nevertheless, occasional patients have been reported who have demented exceptionally early, for example the man described by Rudelli *et al.* (1982) who had a severe head injury at 22, began to dement at 30, and died of Alzheimer's disease at 38 years.

The possibility that there may be a statistical link between Alzheimer's disease and earlier head trauma remains intriguing. This could be explained by increased β -amyloid deposition in the cortex in the wake of trauma (see above). An alternative explanation is that the reduced neuronal reserve brought about by the head injury brings forward the clinical presentation of dementia in those patients who would have developed a dementia anyway, regardless of the head injury. A study of Second World War Navy and Marine veterans found that those who suffered a non-penetrating head injury during the war, compared with those with an unrelated medical condition, were at increased risk of dementia when assessed over 40 years later (Plassman *et al.* 2000). There seemed to be a dose-response effect: mild head injury did not increase the risk, but the hazard ratio for those with moderate head injury was 2.3 (CI 1.04–5.17) and for severe head injury 4.5 (CI 1.77–11.47).

The relationship between head injury and dementia has largely been studied using case-control methodology; the proportion of patients with Alzheimer's disease with a history of head injury is compared with the proportion of normal controls, of the same age and sex, who report having had a head injury. These studies are of course exposed to

reporting bias so the better studies ensure that a matched informant, e.g. a spouse, is used to obtain the history of head injury, both in the case of the patient and the control. It is also necessary to ensure that the controls do not suffer dementia. A meta-analysis of 15 such studies, replicating one of 10 years before (Mortimer *et al.* 1991), found evidence to support the link but the effect was confined to men (Fleminger *et al.* 2003a). For men the odds ratio (OR) of having a history of head injury, for patients with Alzheimer's disease compared with controls, was about 2.

It has been suggested that the risk is related to ApoE status, with those who are $\epsilon 4$ positive being at greater risk (Mayeux *et al.* 1995), although this finding is not consistent (O'Meara *et al.* 1997). Another study using a different methodology also found an effect of ApoE $\epsilon 4$ status (Koponen *et al.* 2004); at 30-year follow-up of 60 patients with head injury, all six patients with dementia were ApoE $\epsilon 4$ positive, whereas only 32% of the total sample were. In the study of Second World War veterans described above there was a non-significant trend towards a stronger association between Alzheimer's disease and head injury in men with more $\epsilon 4$ alleles (Plassman *et al.* 2000).

The special situation with regard to repeated mild head injuries, as sustained during boxing, is discussed later (see Boxing, under Head injuries in sport, later in chapter). For a single head injury it seems likely that the injury does confer a slight increased risk of Alzheimer's disease, particularly in men and probably partly related to the ApoE status of the patient. However, the attributable risk for Alzheimer's disease, as a result of head injury, is small. At most only a small proportion of Alzheimer's disease could be prevented by eliminating head injury.

Aetiology of psychiatric disability after head injury

Over and above any obvious brain damage there are a multitude of factors, constitutional and environmental, that can decisively shape the psychiatric picture in the individual. Such a situation is, of course, common in psychiatric illness, and head-injured patients illustrate particularly well the interplay of many contributory factors rebounding on each other. Confronted with an individual case, clinicians must nevertheless try to decide which are the causal factors presently operating and the relative weights to be given to each, before they can hope to tackle the problem effectively or make a reasoned estimate at prognosis. It will therefore be useful first to review the range of aetiological factors that may contribute to post-traumatic psychiatric disability before describing the common clinical pictures that result. The case in which any one of them operates alone will be rare, and in particular one cannot expect a firm dichotomy between physiogenic and psychogenic causes. Most often the two will be found to be inextricably combined. However, each aetiological factor will first be considered individually

since this is the process that clinical enquiry must follow in seeking to clarify the determinants of disability in an individual case.

Some factors, such as the influence of environmental difficulties, have been readily shown to exert a powerful effect; others, including the effects of brain damage itself, have been more difficult to demonstrate, certainly where symptoms other than cognitive deficits are concerned. However, it is important to avoid the fallacy of concluding that where aetiological factors are easy to demonstrate they are necessarily most potent in action. In particular it is difficult to demonstrate minor degrees of brain damage during life, and one must therefore be wary of dismissing the physiogenic contribution. On the other hand, we must not cling to the possibility that 'subclinical' brain damage is responsible in the face of overwhelming evidence that psychogenesis leads the field.

In the discussion that follows it is equally important to remember that even very large series of head-injured patients are liable to special selection, i.e. ascertainment effects, because of the settings in which they are studied and the populations from which they are drawn. Series derived from acute sources will differ substantially from patients referred later for treatment in rehabilitation units. Patients seen solely in connection with claims for compensation will be different again. All such factors may strongly bias interpretations concerning causal factors. Also the people who suffer head injuries are, to a certain extent, a select group (Haas *et al.* 1987). Premorbid factors may not be determining the outcome of injury as much as the fact that the person got injured in the first place. For example, psychiatric illness increases the risk of suffering a head injury (Fann *et al.* 2002, 2004).

In general, larger effects are found when the series has been selected from late ascertainment after injury; it seems likely that those with chronic sequelae, particularly where there is less in the way of severe injury, will be selectively recruited into these studies, and it is these patients who are more likely to have pre-injury character traits that put them at risk of developing psychological sequelae.

Mental constitution and premorbid personality

The effects of mental constitution and premorbid personality may be manifest in terms of global outcome, or there may be specific effects such that a specific attribute predicts a particular response to injury. An example of this is the common observation that brain injury tends to exacerbate premorbid personality traits. For example, somebody with antisocial personality traits before injury now presents with an antisocial personality disorder after injury, or the presence of obsessional personality traits before injury makes survivors of brain injury vulnerable to obsessive-compulsive disorder (OCD). However, reliable assessments of premorbid mental constitution and personality are hard to make (Ruff *et al.* 1996a) and it is therefore not surprising that different studies have placed differing emphasis on their importance.

Two studies from the 1940s (Lewis 1942; Ruesch & Bowman 1945) looked at the importance of constitutional factors by comparing head-injured patients with non-head-injured patients with neurosis and found a remarkable degree of similarity in constitutional background between the two. Lewis concluded that the 'long-lasting relatively intractable post-concussional syndrome is apt to occur in much the same person as develops a psychiatric syndrome anyway', whereas Ruesch and Bowman noted that the longer the disability persisted, the less likely was it to be the expression of brain damage. Slater's (1943) classic study of 2000 neurotic soldiers also showed the importance of constitutional factors, but here a contribution due to brain damage also emerged; it was clearly shown that soldiers who had sustained brain damage scored lower than average on most items of constitutional vulnerability. Head injury, in effect, appeared to contribute something additional to disturb the overall balance that could be discerned between stress and predisposition in the genesis of neurotic symptoms.

Dencker (1958, 1960) collected 118 twin pairs in which only one of the twins had been injured. The head-injured twins were inferior to their controls on a variety of tests of intellectual function, although the deficits were usually subtle and unobtrusive in everyday life. However, no significant differences were found where emotional and other psychiatric symptoms were concerned. The monozygotic pairs were more concordant than the dizygotic where certain post-traumatic symptoms were concerned – headache, dizziness, impaired memory, sensitivity to noise and decreased alcohol tolerance – suggesting that these at least were founded in genetic constitution rather than in any brain damage that had occurred. Several patients were found to have undergone a 'change of personality' since the injury, with increased tension, fatigability or lessened ability to work, but where monozygotic partners were available for comparison they proved to be closely similar for the traits concerned. Therefore constitutional factors may explain disability that would otherwise have been ascribed to the head injury itself. However, it should be noted that the patients studied by Dencker were examined on average 10 years after injury by which time many of the more specific consequences had probably become submerged. Nevertheless, the findings underline the misleading impression that can be obtained from a cursory psychiatric history. An example of this is a case report of a 9-year-old boy with a history of restlessness and concentration difficulties following a head injury (Nylander & Rydelius 1988). These symptoms were initially attributed to the head injury but examination of his identical twin brother demonstrated very similar behavioural problems.

More recent studies have tended to find less evidence for the role of constitutional factors on outcome after brain injury. This is perhaps best illustrated by Tate's (1998) study in which she examined Symonds' aphorism: 'it is not only

the kind of injury that matters, but the kind of head' (Symonds 1937, p. 1092). In two carefully controlled studies, though with relatively small numbers (total of 20 with poor pre-injury psychosocial functioning), she looked at outcome on average 6 years and 6 months respectively after injury. She found no evidence that those with a history of for example delinquency, criminal convictions or substance abuse did worse following severe head injury, outcome being defined by psychosocial integration and neuropsychometry. In a similar study, Hall *et al.* (1998) examined patients ascertained by admission to inpatient rehabilitation following severe head injury (average length of coma 5–6 days) and also found no difference between those who were at high risk from constitutional factors ($N = 39$) and those who were not ($N = 43$). And in the same year Corrigan *et al.* (1998) showed that it was difficult to predict outcome in the first 5 years after injury, based on pre-injury characteristics, again in those who had been admitted to inpatient rehabilitation.

Some studies have found effects of pre-injury status on outcome. Pre-injury socioeconomic status was found to predict outcome in severe TBI 14 years after injury (Hoofien *et al.* 2002). Novack *et al.* (2001) undertook a sophisticated pathway analysis of contributions from premorbid, injury severity and recovery variables on outcome 1 year after injury in 107 patients with severe head injury recruited from an inpatient rehabilitation unit. Premorbid factors were found to have very significant effects on outcome, partly mediated through their effects on cognitive and functional status at 6 months. However, the premorbid factor was a composite of several measures including age at injury, well known to have a powerful effect on outcome.

There is an impression that it may be easier to demonstrate the effect of mental constitution on the prediction of persistent problems after less severe injury. Thus in a follow-up of Vietnam veterans, which examined those who had suffered head injuries since discharge from the armed forces (Luis *et al.* 2003), there was an effect of pre-injury psychiatric problems on outcome after their mainly mild head injuries. Those with anxiety, depression, mania or psychosis before age 20 were less likely to be in employment when assessed, on average several years after injury, than those without such a history, and more likely to have persistent symptoms of post-concussion syndrome. Ponsford *et al.* (2000), again looking at mild head injury, found that psychiatric problems antedating the injury were more common in those with post-concussion symptoms at 3 months after injury, although the effect was not seen at 1 month after injury. One study in which 60% had a mild head injury found that those due to violence were associated with worse psychosocial functioning before injury, as defined by for example a criminal record or alcohol abuse, and with worse outcome at 1 year (Machamer *et al.* 2003). Deb *et al.* (1999b) following up head injury (82% with mild head injury) found that a history of less education and psychiatric illness before the injury pre-

dicted the presence of a psychiatric illness at 1 year after injury. Other studies looking at mild head injury have failed to find a convincing effect of pre-injury factors, although some of these were weakened by ascertainment effects (Katzmark *et al.* 1995; Cicerone & Kalmar 1997; Savola & Hillbom 2003; Rush *et al.* 2004).

Despite suggestions that particular personality attributes make a person vulnerable to the effects of a head injury (Kay *et al.* 1992), empirical evidence for this idea is limited. Classification into personality types such as psychopathic or neurotic does not add much additional information (Kozol 1945, 1946), although studies with the Minnesota Multiphasic Personality Inventory (MMPI) have indicated that high scores on the hysterical, depressive and hypochondriacal scales are associated with the long persistence of neurotic complaints (Walker & Erculei 1969). Two recent studies have attempted to identify the effects of specific pre-injury personality traits, using the revised NEO Personality Inventory rated by an informant immediately after injury, and found only very limited effects on outcome for both moderate to severe head injury (Malec *et al.* 2004) and mild TBI (Rush *et al.* 2004).

What is the evidence that specific personality features will tend to influence the form that post-traumatic disability takes? Good evidence that a severe head injury will exacerbate prior personality traits or personality disorder is lacking. Malia *et al.* (1995) attempted to objectively demonstrate an effect of four pre-injury personality attributes ('loss of control', 'humour', 'optimism', and 'easy-going disposition') measured retrospectively at the time of admission for neurological rehabilitation. The majority had suffered a severe head injury, but about 20% of the 74 patients studied had brain injury from other causes. Only 'easy-going disposition' before injury was found to have an effect on outcome defined as better psychosocial functioning, and the effect was weak and only observed in those studied within a year of injury. Using the revised NEO Personality Inventory, Kurtz *et al.* (1998) looked for systematic changes in personality by comparing pre-injury scores with post-injury scores, both measured by an informant after injury. No systematic changes were observed; in other words it was not possible to define change in personality based on pre-injury personality.

There is therefore a dissonance between these empirical findings and common clinical observation and opinion which would have us believe that pre-injury personality has a specific effect on outcome. This opinion was enunciated by Kay *et al.* (1992) who anecdotally suggested there were specific patterns of pre-injury personality styles that put patients at risk of a poor response. For example:

The overachiever, who is often obsessive-compulsive and derives his or her sense of self from driven accomplishment, is at risk for a catastrophic reaction.

Grandiose persons get into trouble by being so unable to acknowledge their decrease in ability that they deny it to themselves and others and continue to blunder into situations that evoke failure. The crash of self-esteem, when it comes, is usually catastrophic.

Ruff *et al.* (1996a) presented four case reports to support this line of reasoning. One explanation for the failure of empirical data to validate clinical wisdom could be that the empirical methods used to identify the personality effects are too weak. They almost invariably rely on post-injury assessment of pre-injury characteristics, a method known to be vulnerable to bias. Alternatively, the measures used are simply not tuned to the personality effects that clinicians observe to have predictive value. Possibly clinical wisdom is based on a few convincing cases, but these good exemplars, being few and far between, are not sufficient to produce statistically significant effects when analysed in large cohorts where the majority show little if any effect. Or perhaps clinical wisdom is at fault, and is based on clinicians and informants incorrectly attributing the consequences of brain injury to the kind of head that was injured.

The adverse effects of alcohol abuse before injury are discussed later in this section (see Alcohol and drug abuse and head injury).

The effects of pre-injury IQ are of interest to a resource capacity model of outcome after brain injury (Satz 1993) which proposes that those with greater redundancy of cognitive processing will be less vulnerable to the effects of brain injury. However, inconsistent effects of educational achievement on likelihood of return to work are found. Of more interest, though not easy to interpret, are the findings from the Vietnam Head Injury Study (Grafman *et al.* 1988). An effect of pre-injury IQ was found, but only when post-injury intelligence scores were compared with control subjects who had not suffered a head injury but who were also followed up over 15 years. When head-injured subjects were compared with controls of equivalent IQ, those head-injured subjects with lower pre-injury IQ did worse than their head-injured peers with higher IQ, i.e. they made less gains over their IQ-matched controls than did their more intelligent peers over their controls.

Age at time of injury

Finally, under the heading of constitution it is important to note that many aspects of post-traumatic disability, and especially cognitive impairments, increase with age at the time of injury. This is probably due to the rising incidence of complicating factors such as cerebrovascular disease, the diminishing reserve of neurones, and the general loss of resilience and adaptability among older persons. Mortality also rises sharply. In Kerr *et al.*'s (1971) series of civilian head injuries, a steady rise in mortality occurred after the age of 50, this appearing to be due to age-related factors such as medical complications or pre-existing disease. Pentland *et al.* (1986)

showed that patients over 65 admitted to the head injury unit in Edinburgh with severe injuries were twice as likely to die (77%) as younger patients with the same severity of injury (39%). The elderly with moderately severe injuries were more than twice as likely to remain severely disabled or in a vegetative state (35% vs 14%). Pennings *et al.* (1993) obtained very similar figures in terms of both mortality and disability.

For any given severity of injury, measured by GCS score or length of coma, older patients have longer PTA and worse functional outcome (Katz & Alexander 1994). This effect seemed to begin at about age 40. Stuss *et al.* (2000) confirmed the effect of age on PTA; in those with loss of consciousness of more than 30 hours, those less than 26 years old had a mean PTA of just over 3 weeks whereas for those aged 26 and older the PTA was more likely to be 5–7 weeks. Russell (1932) found that memory difficulties increased regularly with age and were three times as common among patients over 40 as in younger patients. It is therefore not surprising that increasing age is consistently found to have a marked adverse effect on a patient's chances of returning to work. For example, in Heiskanen and Sipponen's (1970) group of severe brain injuries, less than 30% of the survivors aged 50 or over were able to return to their former work, whereas more than 70% of those under 20 were able to do so. Less optimistic figures were found by Brooks, N. *et al.* (1987a) with only 12% of patients older than 45 years returning to work compared with about 40% in those aged 17–30 years. Adler (1945) found that neurotic symptoms, mainly anxieties and fears, were more frequent as age at time of injury advanced, and attributed this to the increased problems of occupational and financial adjustment which had to be faced by older people.

Circumstances of the injury

The circumstances of the accident may have important effects on outcome, as when a reckless driver has injured his family or a workman has been forced against his will to use faulty equipment. The setting may have been peculiarly conducive to fear, anger or resentment as in the following case.

A man aged 48 was coshed on the way to bank his firm's takings and rendered briefly unconscious. For 12 months thereafter he showed enduring symptoms of anxiety and depression despite full physical and intellectual recovery. His ability to function at work appeared to be unaccountably impaired. It ultimately emerged that after a series of frustrating setbacks he had come to be employed in a humble capacity by his successful younger brother who ran a flourishing business. Years of suppressed resentment and hostility were now focused on the injury, and the full significance to him of being attacked while banking the firm's profits immediately became apparent (Lishman 1973).

The concept of cryptotrauma was introduced by Pilowsky (1985) to describe instances in which exploration of the details surrounding the accident can be rewarding in revealing circumstances of special significance. And even ignoring individual determinants of this nature, it is possible to show that disability tends to differ from one broad category of accident to another, whether on the roads, at work or in the home (Brain 1942; Adler 1945; Miller 1966). This may relate to the harmful effects of perception of fault (Rutherford 1989; Wood 2004); those patients who blamed a person or organisation for their injury were more likely to have symptoms. Early emotional reactions after injury (Brenner *et al.* 1944; King 1996), or when the injury has occurred in an emotionally loaded setting (Guttmann 1946), also increase the risk of later problems.

Emotional reaction to the trauma may be one reason why violence-related injury is associated with worse outcome (Wenden *et al.* 1998). However, as noted above, it seems likely that part of this effect is because many of the factors that increase the risk of suffering violence are the same as those that have a negative effect on later outcome, for example alcohol and drug abuse and lower social class (Bogner *et al.* 2001; Bushnik *et al.* 2003; Gerhart *et al.* 2003; Machamer *et al.* 2003).

The emotional repercussions of the accident may be more influential than was supposed at first sight. This is particularly likely when psychiatric disability is disproportionate to the likely severity of brain damage incurred, or when it outstrips expectations derived from a knowledge of previous mental stability:

A woman of 45 was disabled for many months by a number of neurotic complaints after surviving intact from a car crash. The head injury had been mild but her vision had been threatened for a time. Her persistent neurotic reaction was surprising in view of her excellent previous mental health and stability. She eventually confessed to a long-standing secret liaison with the husband of a friend, in whose company the accident had occurred. She had made a fervent resolve to end the relationship by way of atonement if her sight should be spared, and this she was now striving to do. Here the injury served as a focus for long-standing conflict and guilt, in addition to providing ongoing emotional distress of a deeply disturbing kind (Lishman 1973).

In the early stages after injury the patient is vulnerable and often highly suggestible. In particular, he may be strongly influenced by what he hears from fellow patients, the treatment received and how much is or is not explained to him. Protracted investigations can sometimes stir up enduring anxiety.

A policewoman of 22 sustained a minor blow on the head when travelling on duty in a car. Continuing headache led to skull X-ray which showed some increased convolitional markings. A CT scan was therefore undertaken in case a pre-existing hydrocephalus had been exacerbated. This was normal but the foramen magnum seemed enlarged. A myelogram was therefore carried out to exclude any possibility of abnormality at the craniocervical junction and was also normal. Throughout the 6 weeks of investigation her headaches steadily worsened and were still troublesome some 3 years later when she was referred for a second opinion. Her attention had indeed been firmly focused on her early symptoms (Lishman 1988).

Environmental and social difficulties encountered during convalescence and thereafter must always be carefully evaluated because they may be accessible to remediation. Threats to family or personal security and occupational difficulties are likely to be much more difficult for the patient, with their physical or intellectual deficits, to cope with. Fear of returning to a dangerous occupation where the accident has occurred can have a powerful influence in determining prolonged invalidism. Likewise an unstable domestic background or oversolicitude on the part of the family. Tarsh and Royston (1985) have documented the influence of changes within the family in contributing to prolongation of disability, especially overprotection from family members and changes in the normal family hierarchies and roles. Children are particularly vulnerable to the effects of the family environment (see under Head injury in childhood, later in chapter).

Sometimes the problems have been present from before the injury. Selzer *et al.* (1968) were able to show an excess of personal conflicts and stresses in the lives of drivers causing fatal accidents during the 12 months preceding these events, many of which were still affecting the driver at the time. No less than 20% had had an acutely disturbing experience during the preceding 6 hours. An excess of life events in the recent lives of victims of accidental injury has been found (Whitlock *et al.* 1977; Fenton *et al.* 1993).

Compensation, litigation, secondary gain and attribution bias

The important aspects of medicolegal assessment of head injury are dealt with later in this chapter (see Medicolegal considerations). Here it will suffice to note that impending litigation can strongly motivate the aggravation and prolongation of disability. That the compensation issue, like other conflicts, can operate at many levels of consciousness should be no cause for surprise. In some, probably rare cases, there will be entirely conscious simulation for gain, but in the great majority the compensation issue colours the picture in more subtle ways. Once the possibility of compensation is raised

the patient finds himself in complex legal dealings; there are frustrations due to delay, anxieties due to conflicting advice and often capital outlay. In effect the injured person is invited to complain and, having done so, finds he must complain repeatedly, often over years to a number of specialists (Cole 1970).

It is sometimes reported that disability continues until the compensation issue is settled, then clears abruptly whether or not financial reward has been forthcoming (Miller 1961). Even so, improvement on settlement need not imply that the patient has been 'manufacturing' his symptoms: genuine uncertainty and worry have been decisively removed (Merskey & Woodforde 1972). Examples of abrupt resolution on settlement are, in fact, much rarer than is commonly supposed. Steadman and Graham (1970) found that patients whose claims were rejected took a long time to recover or return to work, and 'neurotic resentment' seemed a possible explanation for this. Kelly and Smith (1981) traced 43 of 100 patients to determine the long-term outcome of the post-traumatic syndrome when the compensation issue was at stake; of 26 who had failed to return to work by the settlement date, only one was at work 18 months later, yet all but four had considered the settlement adequate. Rutherford (1989) followed 44 consecutive patients referred for medico-legal reports. At the time of writing the reports 57% had symptoms, but this had fallen to 39% at the time of settlement; there was little further fall in the proportion still complaining (34%) when followed up 1 year later.

Miller (1961, 1966) in reviewing 200 patients seen for medico-legal assessment after head injury estimated that the compensation issue contributes to disability in one-quarter to one-third of all patients. Neurotic disability was twice as common after industrial accidents as after road traffic accidents, and employees of large organisations or nationalised concerns were affected more commonly than those of small intimate firms. Additional evidence of the importance of litigation has been deduced from the fact that post-concussional symptoms are less frequent after injuries at sport or in the home where compensation is not payable (Miller 1969; Rutherford *et al.* 1977). However, before attributing this effect to secondary gain, the possible noxious effects of 'perception of fault' need to be considered (Wood 2004). It is psychologically more traumatic if injury is perceived as being the fault of somebody else, rather than one's own fault or an act of God. And these psychological effects are likely to be even more harmful if there was wanton negligence or a directed assault.

In a clever meta-analysis, Binder and Rohling (1996) compared symptom severity in those who were pursuing compensation with those who were not across 17 studies. The symptoms of those pursuing compensation were worse by on average half a standard deviation (median effect size 0.47). The effect was greater in those with milder injuries. Since then studies have demonstrated that the effect is seen

from as early as a few days or weeks after mild head injury (Feinstein *et al.* 2001; Paniak *et al.* 2002a). However, it must be remembered that only those with symptoms will pursue compensation; those with good outcome will be filtered out of the compensation-seeking cohort, leaving behind only those with worse outcome. Therefore even if the pursuit of compensation does not cause symptoms, the compensation-seeking cohort will always be more symptomatic. And even if compensation is found to causally increase symptoms, this does not necessarily mean that claimants are exaggerating their symptoms. Repeated questioning from lawyers and doctors not only focuses the patient's attention on early symptoms that perhaps were due to recede, but in addition reinforces the prospect of their continuance or of worse to come. Cassidy *et al.* (2004) showed that changes in the law from an adversarial tort system to one of no fault improved outcome as measured by the faster resolution of compensation claims. Nevertheless, some would argue that faster resolution of compensation claims is not in fact a good proxy measure for speedier recovery of symptoms.

If compensation does cause a worse outcome, several mechanisms may be at work. Most difficult to evaluate is the possibility of malingering, a diagnosis perhaps better left to lawyers than physicians (Halligan *et al.* 2003). Nevertheless, patients do sometimes knowingly deceive their doctors, claiming severe disability when little or none exists. In one survey, neuropsychologists estimated that almost 30% of personal injury cases involved probable malingering (Mittenberg *et al.* 2002). Miller and Cartlidge (1972) rather brusquely criticise the unwillingness of doctors to consider simulation, and report a vivid example as follows.

A 30-year-old labourer had sustained a mild head injury without loss of consciousness. During the ensuing months he developed anxiety, depression and stammering, unrelieved by psychotropic drugs, and after a course of electroconvulsive therapy he became totally mute. At the time of examination he had not been heard to utter for nearly 2 years. Numerous referrals had led to a multitude of diagnoses, but 11 psychiatric reports had failed to mention the possibility of malingering.

As can be imagined, examination presented considerable difficulty. The case was well documented and the patient's wife most informative. His own contribution consisted in grimly nodding his head in affirmation or negation of questions and of written notes passed across the table. This he accomplished fluently and accurately. In this manner he registered complaints of frequent headaches, dizziness on change of posture, forgetfulness, and intermittent severe depression. From the beginning of this remarkable consultation it was difficult to escape the impression that the patient was malingering. He was tense, evasive, suspicious

and defensive – and his wife's attitude was very similar. The examiner's conviction that the patient was endeavouring to deceive was so strong that he telephoned a colleague and arranged for him to accompany the claimant unobserved on his mainline train back to the Midlands. The patient exchanged his first remarks with his wife as the train drew out of Newcastle station, and by the time his companion left the train at Durham the whole compartment was engaged in uninhibited and cheerful conversation on matters of the day.

As in this case, malingering often involves two related processes. On the one hand patients lie about the degree to which they are undertaking activities; in other words they are in fact performing activities, e.g. working, but tell their doctor they are not. Only very rarely does this come to light. On the other hand, there may be deliberate simulation; they do very little and pretend to be disabled, whereas in fact they are quite capable of undertaking activities were they inclined to do so. It is this that the clinician is likely to observe at interview. However, confidently distinguishing this pretence from unconscious exaggeration of disability as a result of a conversion disorder (dissociative disorder/hysteria) will often be difficult if not impossible. The parties contesting the claim for compensation will sometimes arrange for covert surveillance of the claimant in order to determine his true level of functioning; this is scarcely appropriate in the context of clinical evaluation, but it is well to be aware that such evidence may be produced.

Motivation factors probably operate at various levels of consciousness. It seems unlikely that the 12 patients with mild head injury examined by Keller *et al.* (2000) in whom there were no unsettled liability claims willfully underperformed on a test of divided attention. Yet the patients' performance improved after they were told that the test result might influence their ability to drive. Neuropsychological evidence that a person's pattern of poor performance on cognitive testing is unlikely to be due simply to brain injury and seems psychologically motivated may be helpful in the evaluation of symptoms (Iverson & Binder 2000). The most convincing demonstration of this comes from forced choice recognition tests, in which the subject has to choose the correct answer from two or more possibilities presented to him. For example, from two faces he has to choose the one that was shown earlier from the one he has not seen before. When a subject chooses significantly fewer correct responses than would be predicted by chance, then this is evidence that the patient probably knows which is the correct one but is, possibly deliberately, choosing the other. Other examples of patterns of responding that suggest underperformance or exaggeration or poor effort include failing on easy tests yet

doing relatively well on more difficult tests, or demonstrating greater variation in performance from one test to another or across the same test measured on different occasions than expected (Strauss *et al.* 1999). Another inconsistency that may be identified is performance on neuropsychological testing that is quite contrary with the patient's performance in everyday life.

If a patient's performance on psychological testing deteriorates over time after injury, quite contrary to the pattern of normal recovery, this suggests psychological forces at work or possibly malingering. However, cognitive decline over time is observed in a small proportion of cases after head injury (see above) for reasons that are not well understood. Sometimes the cognitive decline is attributed to the onset of depression. The effect of depression on cognitive function in patients involved in litigation after a head injury may be measurable but minimal (Sherman *et al.* 2000). Where it was observed it was in the domains of memory and speed of information processing and in those with milder impairments. Others have found the effect of depression to be on executive function (Jorge *et al.* 2004) as well as processing speed and memory (Rapoport *et al.* 2005). However, the interpretation of such cross-sectional studies is undermined by ascertainment effects and issues of cause and effect: does worse cognition make you more depressed, or does being depressed impair cognitive performance? The longitudinal studies discussed in the section on long-term outcome (see above) are therefore of interest. Depression was found to be associated with deteriorating performance both over the first year and over subsequent years. The observation that treating depression after a mild head injury will improve cognition awaits confirmation (Fann *et al.* 2001).

When pursuing compensation it is not sufficient for claimants to demonstrate that they are disabled after the injury. It must be shown that the injury caused the disability. Claimants may therefore be motivated to overestimate their previous health. Indeed this has been demonstrated in patients pursuing compensation after a head injury. They may claim greater academic success before the injury than was in fact achieved (Greiffenstein *et al.* 2002a) and may underestimate the degree to which they were symptomatic before injury (Lees-Haley *et al.* 1996, 1997). As such, patients overestimate the degree to which the head injury is a cause of symptoms. This misattribution may be compounded by 'expectation as aetiology' (Mittenberg *et al.* 1992) whereby people's expectation of the symptoms experienced after a head injury plays a part in determining outcome. Transcultural studies on mild head injury find that far fewer symptoms are reported in Lithuania, a country where there are minimal possibilities for economic gain from a head injury and where the general population do not expect patients to suffer persisting symptoms, than in Canada where personal injury claims are common (Ferrari *et al.* 2001). However, this story is complicated by the observation that the effect of overestimating

one's pre-injury health is common to all patients with a head injury (Hilsabeck *et al.* 1998; Ferguson *et al.* 1999), not just those in litigation, and indeed is common to injured patients, not just those with a head injury (Hilsabeck *et al.* 1998), regardless of cause. As such, it seems that the 'good old days' hypothesis, though less specific, may be more important than 'expectation as aetiology' (Gunstad & Suhr 2001).

Development of epilepsy

Post-traumatic epilepsy develops in about 2–5% of closed head injuries and in over 30% when the dura mater has been penetrated (D'Ambrosio & Perucca 2004). Those with a history of alcohol abuse are particularly vulnerable (Frey 2003). It is also worth remembering that not all seizures after head injury are due to epilepsy (Westbrook *et al.* 1998; Hudak *et al.* 2004), and that prolonged seizures after a mild head injury should particularly raise suspicion of non-epileptic seizures (Barry *et al.* 1998). On the other hand, some head injuries may be due to epilepsy (Zwimpfer *et al.* 1997). The general question of post-traumatic epilepsy is considered in Chapter 6.

The development of seizures represents a serious complication and stands to aggravate the psychiatric disability ensuing from the injury. First there is the socially disruptive effect of the epilepsy, which increases self-concern, hinders rehabilitation and brings special problems in readaptation to daily life. The fits may make their appearance when the patient is on the point of regaining confidence, and represent an added hurdle to be overcome. In addition, the physiological disturbance underlying the epilepsy may add to the effects of brain damage already present. After closed head injury temporal lobe epilepsy is the commonest form (Jennett 1962), and this is the type most frequently incriminated in leading to psychiatric disturbance. However, it has been difficult to demonstrate adverse effects of post-traumatic epilepsy in patients with closed head injury if controls are matched for severity of injury (Haltiner *et al.* 1996), although those with epilepsy tend to require higher levels of nursing care after discharge from rehabilitation (Armstrong *et al.* 1990). Given the potential adverse effects of phenytoin and phenobarbital on cognition and behaviour, it is probably wise that patients with post-traumatic epilepsy taking these drugs are changed to carbamazepine (Wroblewski *et al.* 1989) or valproate. And if these drugs are being used prophylactically to prevent post-traumatic epilepsy, the patient should generally be weaned off them given that there is no evidence for the value of prophylactic therapy (Schierhout & Roberts 1998).

Lishman (1968) found that epilepsy occurred during the ensuing 5 years in 45% of patients with penetrating injuries, and there was a highly significant relationship between its development and the degree of overall psychiatric disability. Epilepsy that developed during the first year after injury was

mainly responsible for the association. The relationship remained significant after controlling for the differing amounts of brain damage sustained among the epileptic and non-epileptic patients. Increased psychopathology in patients with post-traumatic epilepsy was also found in the Vietnam Head Injury Study, though there were no effects of seizure type (Swanson *et al.* 1995). Patients with post-traumatic epilepsy after penetrating injuries may be at greater risk of late cognitive impairment many years post injury (Salazar *et al.* 1987; Walker & Blumer 1989).

Amount of brain damage incurred

The main difficulty in estimating the contribution of brain damage to different forms of post-traumatic psychiatric disability lies in the problem of detecting minor degrees of damage while the patient is alive. The available techniques of neuroimaging, EEG and psychometry cannot be expected always to reflect small amounts of neuronal loss or focal brain dysfunction. A common approach has been to examine the nature and severity of post-traumatic symptoms against clinical indices known to reflect severity of brain damage, such as length of coma, length of PTA, and other clinical features seen shortly after injury. Thus increasing PTA has been found to correlate with increasing evidence of neurological disorder and memory and/or calculation defect, whereas the incidence of anxiety and depression, dizziness sans vertigo, and headache was unaffected by duration of PTA (Russell & Smith 1961).

Intellectual impairment after head injury is readily attributed to brain damage, although even here it is important to be wary of inferring brain damage because of complaints of intellectual impairment and even poor performance on cognitive testing, when all the objective indices suggest a very mild or trivial head injury. When brain damage has resulted in severe cognitive impairment there will of necessity be a significant effect on personality. It is therefore not surprising that personality change has been found to be commoner after the more severe injuries (Steadman & Graham 1970). Patients with moderate to severe dementia after a brain injury are almost invariably impulsive, demanding to have their wants met immediately, at least somewhat thoughtless of others, and often quite suspicious. They will usually prefer routines and are often inflexible. Slow thought processing, poor judgement and lack of spontaneous thought and activity contributes to social withdrawal. The overlap between cognitive impairment and personality change is best illustrated by the dysexecutive syndrome in which the disorder of higher cognition is associated with the presence of persistent behavioural change (Burgess *et al.* 1998). However, even here it may be difficult to be certain that the presence of a reported personality change is due to brain injury, particularly if associated with emotional symptoms and common somatic symptoms, such as headache and dizziness, and where the

symptoms show marked variation over time, e.g. from hour to hour or day to day.

The relationship of overall psychiatric disability to injury severity is less convincing. In Walker and Jablon's (1959) large series the severity of injury appeared to bear some relation to many aspects of psychiatric disorder: impaired judgement, mentation, memory, alterations of personality and even the post-traumatic syndrome. However, in a study of patients 2 years post injury, severity of injury correlated only with impairment of intellectual functions and very little, if at all, with emotional instability or post-traumatic headache and dizziness (Norrman & Svahn 1961). Indeed self-reports of emotional sequelae, measured using the MMPI, have been shown to be more common in those with mild compared with severe head injury (Leininger *et al.* 1991). There may be a complex relationship between injury severity and likelihood of psychiatric sequelae; those with moderate to severe TBI have higher initial risk in the first year, whereas mild TBI is associated with more persistent illness still evident at 3 years (Fann *et al.* 2004).

Lishman's (1968) investigation of 670 soldiers with penetrating injuries used objective measures including X-ray data and surgeons' operating notes to allow direct estimation of the extent of brain tissue destruction. A wide spectrum of psychiatric disabilities was investigated, including intellectual, affective and behavioural changes, also persistent somatic complaints for which no physical basis could be discovered. It was readily shown that simple measures of the amount of brain damage incurred were related to the amount of psychiatric disorder encountered 1–5 years later. This relationship was broadly maintained when allowance was made for effects due solely to intellectual impairment. When PTA was used as an index of diffuse as opposed to focal brain damage, again regular correlations were seen with the severity of eventual psychiatric disability. The components of psychiatric disability that were particularly closely tied to the indices of brain damage included apathy, euphoria, and behavioural disorders such as disinhibition, facile or childish behaviour and lack of judgement and consideration for others. Among symptoms which had apparently contributed little if at all to the relationships with brain damage were difficulty in concentration, depression, anxiety, irritability, and somatic complaints such as headache, dizziness, fatigue and sensitivity to noise. Difficulty with memory occupied an intermediate position, suggesting a more variable aetiology: some patients suffered principally from organic disturbance of memory and some from psychogenic elaboration of minimal defects.

Nevertheless, the correlations between brain damage and psychiatric disability, while highly significant statistically, were relatively small (correlation coefficients in the region of 0.25). In other words, brain damage could be shown to con-

tribute little more than one-fifteenth part of the total causation of psychiatric disability in the material.

Alcohol and drug abuse and head injury

Waller (1968), investigating road deaths in California, found that 58% of drivers, 47% of passengers and 36% of pedestrians had alcohol in the blood, most with levels exceeding the legal maximum for drivers. Moreover, 75% of the drivers could be classified as problem drinkers. In the UK it has been estimated that one-quarter of all road accident deaths are associated with alcohol (Raffle 1989). In an urban trauma centre perhaps 40% of head injuries are in those with a history of heavy drinking (Kolakowsky-Hayner *et al.* 1999). The prevalence of head injury in alcoholic subjects is some two to four times that of the general population (Hillbom & Holm 1986). Alcohol, particularly binge drinking, is associated with assaults and falls (Savola *et al.* 2005), whereas drug abuse may have a more particular association with assaults (Corrigan *et al.* 1995).

The ways in which acute alcohol intake can increase the extent of brain injury, and chronic intake can delay reparative processes within the nervous system, are now appreciated from laboratory experimental studies (Albin & Bunegin 1986). There are many other reasons why those with a history of alcohol dependence might do worse after a head injury including the known effects of alcohol dependence in the absence of a head injury to produce cognitive impairment. However, not all studies find that an elevated blood alcohol at the time of injury predicts a worse outcome once injury severity measures of depth or length of unconsciousness have been controlled (Nath *et al.* 1986; Alexander *et al.* 2004). This may be because those who are intoxicated will, for any given severity of TBI, have deeper and more prolonged unconsciousness; their conscious level is suppressed by the sedative effects of alcohol. Thus when matched for injury severity using measures of conscious level, intoxicated patients may have similar outcomes, despite potential deleterious effects of alcohol on outcome. As a group, patients who are blood alcohol positive on admission tend to have lower GCS scores (Chatham-Showalter *et al.* 1996).

Nevertheless many studies do demonstrate the adverse effects of alcohol on functional outcomes. This may be explained by greater cerebral atrophy in patients with either a history of alcohol dependence or a positive blood alcohol at admission (see Neuroimaging and head injury, earlier in chapter), and there is evidence that for any given level of physical trauma those who are intoxicated have more severe evidence of brain injury on CT (Cunningham *et al.* 2002). Patients who resume alcohol abuse have less medial frontal grey matter, impaired performance in executive tasks, and are less likely to return to work (Jorge *et al.* 2005).

Brooks *et al.* (1989) found that alcohol intake at injury was a significant predictor of the severity of memory impairment

2–6 years later. Moreover, there was an interaction between the severity of the injury and amount of alcohol consumed on the size of the memory deficit; to have a short PTA and to have drunk heavily led to a worse outcome than occurred in patients with a considerably longer PTA who had drunk lightly or not at all.

In Brooks *et al.*'s (1989) study the deleterious effects of drinking at the time of the accident emerged more clearly than the effects of habitual consumption, although the two were strongly interrelated. However, Rönty *et al.* (1993) have shown the effects of habitual excessive consumption on CT measures of brain damage in 56 consecutive patients with mild or moderate injury, including 15 alcohol abusers and 41 without alcohol problems. The groups were comparable in terms of age and severity of injury. The alcohol group showed markedly larger initial volumes of brain injury on CT. On rescanning 6 months and 1 year later the alcohol groups had developed more local brain atrophy, and greater ventricular and sulcal enlargement, despite equivalence on these measures with the non-alcoholic group at the time of injury. Only 40% of the alcohol group returned to work after the injury compared with 73% of the remainder. A deleterious effect of alcohol intoxication at the time of injury on neuropsychological test performance in the months after injury, independent of the effects of a history of pre-injury alcohol abuse, has been found (Tate & Broe 1999). Over 50% were intoxicated at the time of injury and these patients did worse on tests of memory and block design, after controlling for injury severity and history of alcohol abuse. Alcohol and drug misuse before injury increase the risk of mood disorder after injury (Dikmen *et al.* 2004; Jorge *et al.* 2005).

In view of the close association of head injury with alcoholism, it is worth having a low index of suspicion for its role in many of the sequelae of head injury. It is associated with subdural haemorrhage (Sonne & Tonnesen 1992). Agitation requiring restraint in the early post-injury period is more common in those with a history of alcohol use (Edlund *et al.* 1991) and may be related to an alcohol withdrawal syndrome. It is easy to miss Wernicke–Korsakoff syndrome in a patient recovering from head injury, yet treatment with thiamine might ameliorate at least some of the cognitive impairment. There is therefore something to be said for routinely prescribing thiamine in patients with a head injury with a history of alcohol dependence (Ferguson *et al.* 1997).

It is not uncommon to observe patients with a prolonged and severe history of alcohol dependence before injury to be apparently cured of alcohol dependence while on an inpatient rehabilitation unit. For many months after the injury they show no sign of craving or interest in alcohol. However, this happy state of affairs does not always last. As former cues are reintroduced when they begin to take visits into the community past pubs and off-licenses, and re-establish former friendships and generally become more active, drinking behaviour often returns. Nevertheless, there may be a

tendency for the proportion of patients with drinking problems to decrease after brain injury (Kreutzer *et al.* 1990). Bombardier *et al.* (2003) compared subjects' drinking habits in the year before and the year after a head injury. In the year before 41% were rated as heavy drinkers, but this had reduced to 17% in the year following injury. They found little evidence of new cases of alcohol dependence arising in the post-injury year. However, when followed up for 30 years almost 12% of patients were found to have developed alcohol abuse not previously present (Koponen *et al.* 2002). In a study looking particularly at drug abuse, there is evidence that there may be some who only take to drug abuse after the injury, and might not have done so had they not been injured (Hibbard *et al.* 1998).

Location of brain damage incurred

Many investigations have sought to determine how far psychiatric disability depends on the location of damage within the brain. Studies examining the correlations between neuroimaging and outcome in closed head injury are discussed in Neuroimaging and head injury, earlier in chapter. However, closed head injury is not a good model for predicting brain–behaviour relationships because of the diffuse nature of the insult. On the other hand, penetrating injuries are more suitable for analysis, though even here it must be recognised that damage may exist where it is unsuspected.

Teuber (1959, 1962) and coworkers investigated cognitive and perceptual defects in a large series of penetrating injuries with regional brain damage. Patients with left parietotemporal lesions showed significant losses on the AGCT of general intelligence when pre- and post-traumatic scores were compared. No such losses were found after lesions elsewhere. The differences persisted after excluding patients with dysphasia.

Hillbom's (1960) important investigation surveyed a large number of wartime head injuries, of which 415 were randomly selected for special study. Among unilateral wounds, the left were associated with more psychiatric disturbance than the right, particularly where dementias and psychoses were concerned. Patients with parietal, occipital and cerebellar lesions were relatively free from psychiatric disturbance.

Lishman (1968) also found left hemisphere lesions to be more closely associated with overall psychiatric disability than right hemisphere lesions and patients with injury to the left temporal lobe were particularly at risk. However, intellectual disorders were found more commonly after left hemisphere damage, while affective disorders, behavioural disorders and somatic complaints were more frequent after right hemisphere damage (Table 4.4). Intellectual disorders were especially associated with damage to the parietal and temporal lobes, whereas affective disorders, behavioural disorders and somatic complaints were more frequent after frontal lobe damage. Sexual disturbances were seen only after frontal wounds, and with one exception this was also

Table 4.4 Symptoms and symptom groups seen 1–5 years after penetrating injury in relation to location of brain damage. (After Lishman 1968.)

	No. of cases (total 345)	Hemisphere		Lobe(s) (right, left or both)

true of criminal behaviour. The 'frontal lobe syndrome' (recorded for patients who showed euphoria, lack of judgement, facile or childish behaviour or disinhibition) was especially common after frontal wounds, but 9 of 32 examples were found after wounds which did not apparently involve the frontal lobes at all.

In the Vietnam Head Injury Study, right orbitofrontal injury was associated with increased edginess, anxiety and depression, whereas left dorsolateral frontal lesions showed greater anger and hostility (Grafman *et al.* 1986a). The literature on the behavioural consequences of patients suffering head injuries in the world wars, which also demonstrated locaton-specific effects, will be reviewed in detail below.

There is therefore support for the broad generalisation that lesions in some areas provide a greater psychiatric hazard than others, and that this involves emotional and behavioural disturbances as well as cognitive defects. Nevertheless, it seems likely that in general the amount of brain damage incurred is more important than its location in determining outcome (Grafman *et al.* 1986b).

Categories of post-traumatic psychiatric disorder

The many different forms of post-traumatic psychiatric disablement cannot be rigidly classified, and complex admixtures of symptoms are frequently seen. For example, changes of temperament may occur along with intellectual impairment, or paranoid developments may arise in association with neurotic disability. Quite often, however, specific features or a combination of related features are outstanding, or even seen in relative isolation. For this reason the four main categories of psychiatric disturbance are examined separately: cognitive impairment, change of personality, psychosis, and affective disorders. The problem of the so-called post-concussion syndrome will be dealt with separately, alongside a discussion of outcome after mild head injury.

The relative frequency of these changes may be gauged from the analysis of two large series of patients in which these broad divisions have been observed. Hillbom's (1960) follow-up of 3552 wartime injuries, of which 1505 were

penetrating, showed cognitive impairment in 2%, changes of character in 18%, psychoses in 8% and severe neuroses in 11%. Ota's (1969) large series of 1168 closed head injuries among Japanese civilians showed cognitive impairment in 3%, changes of character in 6%, psychoses in 5% and neuroses in 22%. The frequency of cognitive impairment will depend heavily on the severity of brain injury studied. For example, half of patients with severe head injury will have memory impairment (Levin 1990).

More recently, standardised diagnostic assessments have ascertained the frequency of Axis 1 mental disorders after closed head injury. High rates of depression and anxiety disorders were identified in patients with a head injury attending a brain injury rehabilitation outpatient clinic; 26% had a major depressive disorder and 24% generalised anxiety disorder (Fann *et al.* 1995). Using the Structured Clinical Interview for DSM-IV Diagnoses (SCID) in community-dwelling survivors of head injury on average 7 years post injury, strikingly high rates of depression and anxiety disorders have been found (Hibbard *et al.* 1998): 80% were diagnosed as suffering any Axis 1 disorder, with 61% having major depression and 9–19% one or other of the anxiety disorders; 28% had a substance use disorder. Using a robust method of subject ascertainment, Deb *et al.* (1999b) found that in a consecutive series of 120 patients aged 18–64 years admitted to a hospital following a TBI, at 1 year post injury 14% had an International Classification of Diseases (ICD)-10 diagnosis of depressive illness and 9% panic disorder, higher rates than in the general population. Comorbidity is common; in one study half of patients with major depression also had generalised anxiety disorder (van Reekum *et al.* 1996). Patients with TBI, compared with age- and sex-matched controls, have more psychiatric illness both before and after the head injury (Fann *et al.* 2004). The database of the NIMH Epidemiologic Catchment Area Study has been analysed to compare lifetime rates of psychiatric illness in those who reported that they had suffered a head injury with loss of consciousness, with controls (Silver *et al.* 2001). Increased rates of depression (11% vs 5%), anxiety disorders (e.g. panic disorder 3.2% vs 1.3%), alcohol (24% vs 10%) and drug abuse (11% vs 5%) were seen. It was not possible to say if these disorders antedated or postdated the head injury. What is perhaps surprising from these studies is the relative lack of reporting of post-traumatic stress disorder.

Cognitive impairment

More severe head injuries are likely to be followed by persisting cognitive impairment of a degree proportional to the amount of brain damage incurred. In closed head injuries a PTA of 24 hours may be taken as a very approximate clinical guide; below this, complete intellectual recovery may be expected in a fair proportion of cases, but with durations in excess of 24 hours the patient will be fortunate to escape

without some intellectual impairment. With penetrating injuries the length of PTA is a less reliable guide. In these cases concussion and amnesia may then be brief or absent, yet focal cognitive defects can be severe, especially if haemorrhage or infection have occurred. With increasing age intellectual impairment becomes more likely. Damage to the dominant hemisphere will generally produce more severe effects on intellectual function than damage to the non-dominant hemisphere (Teuber 1959, 1962; Piercy 1964).

As in almost all cases of diffuse brain damage, the hallmarks of the cognitive impairment of closed head injury are psychomotor slowing, difficulties with attention and concentration and memory, and impairment of executive function. In cases where the only finding was diffuse axonal injury the most frequent impairments were in memory and executive function, but no cognitive domain was consistently spared (Scheid *et al.* 2006).

Impairments of speed of information processing, capacity for information processing, attention and executive function go hand in hand and many of the common cognitive symptoms of closed head injury can be understood as arising from their selective vulnerability. The result is slowness over tasks, inattention due to overload, and distractibility due to lack of spare capacity for the monitoring of irrelevant stimuli; working memory is impaired (McDowell *et al.* 1997). These symptoms overlap with those described as part of the dysexecutive syndrome: lack of fluency and problems with dual-task processing and multi-tasking, organising, planning and prioritising, switching from one task to another, inhibiting behaviour and adapting to novel situations, abstract reasoning and judgment, and with monitoring.

Dissecting out the contribution of the psychological processes underlying these various symptoms is not easy. For example, the attentional problems that follow brain injury are multifaceted and overlapping. They include alterations in alertness, psychomotor slowing, distractibility, impaired sustained attention and difficulties switching attention (van Zomeren *et al.* 1984; Gronwall 1987, 1989; Stuss *et al.* 1989). The degree to which these various facets of attention share common processing impairments is uncertain. It seems likely that while slowed speed of information processing is central to many attentional problems (Ponsford & Kinsella 1992), it cannot account for all (Whyte *et al.* 1995). So, for example, impairments of those aspects of attention related to executive function (Spikman *et al.* 1996) are observed independent of slowing.

Simple reaction times are not a good indicator of injury severity and more complex tasks are more likely to show evidence of psychomotor slowing. The PASAT taps many of the cognitive processes related to slowing of information and working memory and is particularly sensitive to head injury (Tombaugh 2006). It has been suggested that delayed processing speed is particularly likely when interhemispheric information procession is required (Mathias *et al.* 2004b).

Likewise dual-task processing impairments may be particularly vulnerable to diffuse brain injury (Vilkkil *et al.* 1996), suggesting that it is damage to the white matter tracts that interferes with the networks necessary for information processing and attention.

Executive disorder after head injury is also multifaceted and the tests used to measure it overlap with tests of 'frontal lobe function'. No one single measure of executive function seems adequate to capture the various impairments and behaviours that may be described as being part of the dysexecutive syndrome (Bamdad *et al.* 2003). The Behavioural Assessment of Dysexecutive Syndrome (BADS) (Wilson *et al.* 1996), which has tests requiring the subject to impose a plan to solve the task rather than simply having to follow rules, was developed as a sensitive measure. In fact, multiple tests, including more traditional tests of frontal executive disorder such as Wisconsin Card Sorting Test (WCST), Trails B, verbal fluency and the Stroop, as well as BADS, may be necessary to detect all patients with evidence of executive problems (Bennett *et al.* 2005).

As a general rule, patients after closed head injury may show impairments on frontal lobe tests or tests of executive function, in the absence of any evidence of impairment of IQ; it is therefore essential to have undertaken tests of frontal or executive function, for example BADS, before ruling out evidence of cognitive impairment. Some patients with good evidence in day-to-day life of disorganised thinking due to brain injury will nevertheless perform well on standard frontal executive tests. Impairments may only be evident for tests which replicate the unstructured demands of everyday life (Shallice & Burgess 1991); tests of shopping performance seem to be particularly telling (Alderman *et al.* 2003) (Fig. 4.6).

The growing literature on the cognitive processes, located particularly in medial orbitofrontal lobe, involved in decision-making in relation to goal-directed behaviour (Kringelbach & Rolls 2004) helps explain how impairments of cognition overlap with changes in behaviour and personality (Damasio 1996). For example, central executive deficits measured using dual-task processing may be related to

Fig. 4.6 Multiple Errands Test. Patients are given the task of buying items in a certain order, with additional rules that they have to follow. (a) The systematic path of a healthy control patient undertaking the task in a pedestrianised street. (b) The disorganized path of a patient with a dysexecutive syndrome who undertakes the task in an inefficient manner and breaks the rules. (Courtesy of Professor Paul Burgess.)

behavioural dyscontrol (Alderman 1996). Abnormal performance on a gambling test may be associated with personality change (Levine *et al.* 2005).

Memory is also disproportionately affected in relation to intellectual function (Levin *et al.* 1988). Several problems are characteristic of the memory impairment of closed head injury (Baddeley *et al.* 2002). Inaccurate recall of memories is probably partly related to problems with source memory, in other words identifying the context in which a memory is embedded. One consequence is intrusions, for example recalling a word from the wrong word list. Confabulations are common and lack of insight for the memory disorder is almost universal if confabulation is marked. Problems with executive function probably partly explain why patients have problems with memory recall (Vanderploeg *et al.* 1994), perhaps because of a failure to apply active strategies to help recall. Impairments in executive function may also contribute to the impairments seen in prospective memory, i.e. the ability to remember to do something (Kinsella *et al.* 1996).

Language and communication problems are quite common, though pure aphasic syndromes are not. Many patients complain of word-finding difficulties. Deficits in executive function and social cognition contribute to the communication difficulties, for example patients often show impairments in understanding of metaphor or faux pas (Milders *et al.* 2003). Improvement in aphasia is sometimes quite marked, whether after penetrating injury (Walker & Blumer 1989) or closed head injury (Thomsen 1984). Verbal IQ is more resistant to the effects of closed head injury than is performance IQ and it is therefore not unusual to see a significant discrepancy between verbal and performance IQ, particularly for those measures which are timed. On the other hand, insight into any cognitive impairment and any accompanying behavioural change tends to be lost early, and this often has a marked bearing on the patient's capacity to manage their finances and affairs for example.

All gradations are seen, ranging from established severe post-traumatic dementia to minimal degrees of intellectual impairment that may come to light only when the patient returns to work. After very severe closed head injury the impairment of intellect is usually global, affecting a wide range of cognitive functions together. Marked post-traumatic dementia is usually accompanied by hemiparesis, quadriparesis or other striking neurological disablement. In the most severe cases the patient remains mute and immobile on recovery from coma, persisting thus until death supervenes, often within a year. This is the *persistent vegetative state*, which represents the most severe form of disability compatible with survival (Jennett & Plum 1972; Andrews 1999; Bates 2005). The sleep-wake cycle is preserved, indicating that the patient is no longer comatose, but all mental function appears to be lost. The eyes may be open and blink to menace or follow moving objects, but they are not attentive. Liquids placed in the mouth may be swallowed. Beyond

this, however, responsiveness is usually limited to primitive postural and reflex movements of the limbs. Such a condition represents essentially a state of wakefulness without awareness. The similarity to akinetic mutism is obvious, though in the latter the potential for responding may be considerably greater. The most important differential diagnosis is a locked-in syndrome. In these patients the ability to communicate is lost, yet conscious awareness and thought is relatively spared. Therefore every attempt to establish communication with the patient, for example using eye blink to indicate 'yes/no', needs to be explored. PET scanning may demonstrate reduced cerebral cortex blood flow (Menon *et al.* 1998). The difficult ethical and legal problems surrounding the point at which life-sustaining treatment might possibly be withdrawn are discussed by Howard and Miller (1995). The responsible lesions may lie in the cortex, thalamus or brain stem, with diffuse white matter damage being universal at autopsy.

Short of this, the patient is profoundly slow and apathetic, frequently with incontinence and gross dysarthria. All intellectual processes are severely affected and even recognition of relatives may be long delayed. These patients are described as being in a minimally conscious state (Giacino & Whyte 2005). Further recovery often brings evidence of emotional lability, with episodes of uncontrolled weeping or laughing, or more rarely with outbursts of poorly coordinated aggressive behaviour. The 'catastrophic reaction' may be called forth when the patient is confronted with a task beyond his ability, with sudden flushing, restless overactivity and either explosive anger or weeping. In one very severely injured patient, eye-contact caused dramatic distress and opisthotonic posturing, and was associated with a decline in the overall condition (Fleminger *et al.* 1996).

Slow improvement over many months or sometimes years may be expected in all but the most severe examples. Apathy or empty euphoria may remain as persistent features. Logical and abstract thinking will be most markedly affected as in other forms of dementia. Blunting of affect and loss of libido is the rule, and paranoid developments are not uncommon.

Focal cognitive impairment

A focal emphasis of brain pathology may result in focal cognitive deficits, which either stand out against a background of general intellectual impairment or on occasion appear in highly circumscribed form. Strictly focal deficits are more likely after penetrating injuries than closed head injuries, but nonetheless the search for focal emphasis in disorder must always be pursued. A dysphasic or an amnesic syndrome can readily come to be mistaken for global dementia. Areas of relatively intact cognitive function must always be demarcated so that they can be used to the full in rehabilitation.

Selective impairment of memory may persist despite excellent restitution of other intellectual functions. This

may be sufficiently marked to constitute a 'post-traumatic Korsakoff syndrome', and presumably depends on circumscribed damage to structures in the diencephalon or medial temporal lobe structures.

It is unfortunately true that when focal deficits are very marked and persistent, in patients with closed head injury the likelihood of impairment in other areas of intellectual function is high. However, in penetrating injuries, for example due to high-velocity missiles, highly selective impairments in language, visual perception and spatial orientation persisting 20 years after injury, yet without any evidence of generalised intellectual deterioration, may be seen (Newcombe 1969).

Change of personality

Change of personality implies an alteration in the patient's habitual attitudes and patterns of behaviour, so that his reactions to events and to people are different from what they were before. This may occur as a persistent sequel of head injury and is undoubtedly one of the most distressing after-effects for the families of the victims. The patient may be aware of the change in himself, though quite often he is completely oblivious of it. Sometimes the alterations are gross and obvious, or sometimes detectable only to those who knew him well beforehand.

The term is used to cover a wide variety of disturbances that can be hard to evaluate or to classify with precision. Such disturbances may overlap with changes in cognition, or with persistent changes in mood. Accordingly, this area of post-traumatic change is particularly difficult to interpret. Aspects of the pre-traumatic personality will usually be found to colour the picture, and many of the changes will represent intensification of traits that were present all along. Sometimes, however, as with frontal lobe damage, there will be elements of change that are new and broadly similar in all individuals affected. Sometimes the changes will be determined by brain damage, sometimes by psychogenic factors and sometimes by a combination of the two. Where brain damage is insubstantial, the stress of the accident and its subsequent repercussions will often be found to be the factors mainly responsible, acting on special vulnerabilities in the person concerned.

Alexander (1982) points out that head injury is particularly prone to damage the neocortical portions of the limbic system: the frontopolar, orbitofrontal and anterior temporal regions (see Fig. 4.1). Few other pathologies routinely damage such areas in a symmetrical fashion while largely sparing the rest of the neocortex. This may explain why behavioural problems are often greatly out of proportion to the severity of neurological defects, and why profound changes in behaviour, affect and emotion can occur even when there is little by way of long-term cognitive impairment.

Nevertheless, the personality change after brain injury is heterogeneous. Lezak (1978), on the basis of her extensive experience, suggested five broad and overlapping categories of personality change:

- impaired capacity for social perceptiveness;
- impaired capacity for control and self-regulation;
- stimulus-bound behaviour producing difficulties in initiating and planning behaviour;
- emotional alterations, particularly apathy, silliness and lability;
- inability to profit from experience.

However, when standard criteria are applied to describe typical personality disorders following head injury, a somewhat different picture emerges. For example, of 60 patients with head injury (half of whom had severe or very severe injuries) followed up 30 years after injury, 23% were found to have a personality disorder (Koponen *et al.* 2002). The most frequent were avoidant (15.0%), paranoid (8.3%) and schizoid (6.7%). Another study rated two-thirds of patients to have a personality disorder, the most frequent being borderline, avoidant, paranoid, obsessive-compulsive and narcissistic disorder (Hibbard *et al.* 2000). The association with borderline personality disorder is in keeping with the finding that 40% of men presenting with borderline personality disorder give a history of head injury, compared with only 4% of controls (Streeter *et al.* 1995).

In Roberts' (1976, 1979) survey of the long-term outcome of severe head injuries, the commonest pattern of personality change had a distinctly frontal character. This he termed 'fronto-limbic dementia', a combination of disabling euphoria, disinhibition or anergia, associated in the majority of cases with intense irritability. Marked examples were seen only after very severe injuries. Memory was usually also very defective. Less commonly, the frontal personality change was present without undue irritability. Occasional patients indeed could be said to have shown *improvement* in personality, in that they were now less prone to worry and were more outgoing and sociable.

Personality change and location of injury

Frontal lobe lesions remain the best-known example of the effects of regional cerebral damage on personality. However, two important questions emerge. First is there evidence that frontal injury, either bilateral or unilateral, as opposed to injury to other parts of the brain, is particularly likely to cause a change in personality? If so, is it possible to determine any associations between the sort of personality change observed and the localisation of the lesion within the frontal lobe?

The first observation that indicated that personality change might be particularly likely after frontal as opposed to other brain injuries was perhaps the case report of Phineas Gage. He was injured by an iron bar which passed through his frontal lobes and caused profound personality change (Harlow 1868). Then, in a study of historical importance,

Phelps (1898) investigated the site of laceration of the brain at autopsy and compared this with the presence or absence of mental abnormalities immediately before death in a series of head-injured patients. Among 225 autopsies, mental change had existed in only four cases where lacerations had spared the left frontal lobe. Furthermore, among 28 cases with frontal lobe laceration, abnormalities had been noted only when the left lobe was damaged.

Since then extensive series of patients with penetrating head injuries have been investigated after each world war. Unfortunately, many of these studies relied heavily on impressionistic statements. Nevertheless, Feuchtwanger's (1923) study provides strong support for the selective effects of injuries that are frontal as opposed to non-frontal. He compared 200 frontal gunshot wounds with 200 cases where bullets had penetrated other parts of the skull. The outstanding changes in the frontal group included euphoria, facetiousness, irritability, apathy and defects of attention. There was often an incapacity for planning ahead, tactlessness and moral defects. Where intellect was disturbed this seemed usually to be secondary to disorders of emotion and volition. Support for these findings came from Hillbom (1960); character change was observed in 43% of those with frontal injury as opposed to 25% across the whole group of brain injured. Lishman (1968) identified 32 patients who showed euphoria, lack of judgement, facile or childish behaviour or disinhibition; this 'frontal lobe syndrome' was especially common after frontal wounds, but 9 of the 32 appeared to have no involvement of frontal lobes at all. Grafman *et al.* (1996) found that patients from the Vietnam Head Injury Study with injuries only involving frontal lobe, compared with those with injuries not involving frontal lobe, were more likely to show aggression; for example 19% as opposed to 8% were rated as having threatened to injure others. Others have noted the liability of frontal lesions to produce changes of character that led to criminality (Lindenberg 1951; Mutschler 1956). Kleist (1934) added loss of initiative, spontaneity of motor activity, lack of ideation and mutism as characteristic of frontal injuries.

We can therefore confidently assert that injury to the frontal lobes carries a particular risk of personality change, and that the personality change tends to have particular characteristics. However, consistent effects of laterality of lesion have not been found. The special psychiatric hazard of bifrontal injuries has been noted (Heygster 1949), although this may at least in part be because medial and orbital frontal lesions are particularly likely to be bilateral.

Are there any selective effects of the site of injury within the frontal lobe? Differences have been described between wounds of the convex lateral surface and wounds of the orbital parts of the lobe, the former producing mainly intellectual and motor changes while the latter had more serious effects on the personality (Kleist 1934; Faust 1955, 1960; Walch 1956). Walch was able to compare 117 cases with orbit-

ofrontal injuries with 185 frontal injuries not involving orbitofrontal cortex. Disinhibition was common to both but those with orbitofrontal injuries remained 'indifferent to every attempt at guidance' and a high proportion showed changes in 'the more highly developed qualities of personality'. On the other hand, lack of drive was more associated with convexity lesions. Faust similarly stressed the lack of productive thinking, indifference and incapacity for decisions with convexity lesions. Patients with orbital lesions often failed to show defects on formal intelligence testing, but were prone to develop marked personality changes.

In line with these observations Blumer and Benson (1978) proposed two types of personality change after frontal injury. One in which apathy and indifference were marked was termed 'pseudodepressed'. This was associated with convexity lesions, and also injury to basal ganglia and thalamus and their connections. On the other hand, orbitofrontal lesions might produce a 'pseudopsychopathic' personality with changes in the direction of puerility and euphoria. The patient lacked adult tact and restraint and might be coarse, facetious, hyperkinetic or promiscuous. Irritability and impulsive antisocial behaviour could be seen. More recent investigations into social cognition, decision-making and control of goal-directed behaviour lend support to the notion that damage to orbitofrontal or ventromedial cortex might result in such disturbance of social behaviour (see below).

In view of the close proximity of the cribriform plate to the medial orbitofrontal cortex, it is not surprising that some patients with disturbance of social cognition associated with damage to medial orbitofrontal cortex also have anosmia (Cicerone & Tanenbaum 1997) (Fig. 4.7). Anosmia is associated with injury to orbitofrontal cortex (Yousem *et al.* 1999). Anosmia may be associated with impairment of executive function (Callahan & Hinkebein 1999), and with hypoperfusion of orbitofrontal cortex (Varney *et al.* 2001). However, the observation that anosmia is particularly associated with antisocial personality change after head injury (Varney 1988) has not been replicated (Greiffenstein *et al.* 2002b).

The picture just described has obtained recognition on account of the uniformity of the changes seen from case to case. Frontal lobe personality change bears a definitive stamp which in large measure cuts across differences in premorbid personality. However, less is known about specific personality changes that may follow circumscribed lesions of other parts of the brain. Temporal lobe injuries appear to show a special frequency of personality disorder, both in their own right and by virtue of the temporal lobe epilepsy which may accompany them (Ajuriaguerra & Hecaen 1960).

Injury to the basal parts of the brain also attracted special attention. Kretschmer (1949, 1956) described a 'basal syndrome' which found wide support in the German literature. This results from lesions of the midbrain, hypothalamus and orbitofrontal cortex. It is characterised by sluggishness and apathy along with fluctuations of mood and sudden out-

bursts of irritability, typically coupled with disturbance of fundamental drives and instincts – appetite, thirst and sleep rhythm – and varied sexual pathologies. Hoheisel and Walch (1952) described five patients with marked bipolar fluctuations of mood persisting for a long time after head injury; one such case had a shell splinter in the hypothalamus and the other four showed clinical signs that indicated diencephalic injury.

Personality change and cognitive impairment

In those with severe brain injury the personality change will often be but one aspect of the global dementia which follows injury, and cognitive deficits of some degree will be in evidence. With more severe dementia there will be slowing, impairment of motivation, loss of libido and withdrawal of interest in surrounding events and people. Emotional changes include blunting, instability, apathy or euphoria.

Fig. 4.7 Personality change after head injury associated with medial orbitofrontal damage. A 33-year-old plumber was involved in a fight and was knocked to the ground. He was unconscious for about 5 minutes and was admitted to hospital for a few days. He was never able to return to his job. He became disorganised and lacking initiative and drive. He came to rely entirely on his girlfriend and a good friend for support, e.g. to manage his finances and get him to appointments. He developed a severe constant headache and threatened violence against his doctors for not being able to help him. The CT brain scan (a) was reported as normal and he was turned down for both Disability Living Allowance and by the Criminal Injuries Compensation Authority; his disability was regarded as a gross over-reaction to a mild and relatively trivial head injury. At 5 years post injury he had a full neuropsychiatric assessment which noted that he had been anosmic ever since the injury, and that in the first few days in hospital after the injury he was confused and occasionally walked around the ward naked. MRI identified a lesion of the medial orbitofrontal lobe bilaterally: (b) T2 weighted; (c) sagittal section T1 weighted; (d) coronal section T1 weighted. This had in fact been evident on the CT scan as a hypodense area, but was presumably regarded as artefact. Because it was now evident that his personality change and dysexecutive disorder was due to a traumatic lesion of the brain, he was successful in appealing for disability allowance and compensation. Five years later, 10 years after the injury, he continues to lead a dependent life, is unemployed, only going on holiday when taken by his friends, has split with his girlfriend and now lives with his mother. He gets quite depressed at times but remains grateful that the cause of his problems has been properly established.

Irritability and explosive anger occur in some cases and paranoid developments in others. A passive and childish dependence may develop, with petulant behaviour and egocentricity. In very severe examples the essential individuality of the person may be to a large extent obscured.

The changes that accompany intellectual impairment may be no more than a loss of refinement or lessened vitality of behaviour, sometimes seen only as transient disturbances which gradually recede over the months that follow. Even so these may combine with adverse circumstances in marriage or at work to set in train severe problems for the patient and his family. With minor degrees of intellectual loss the change may be understandable in terms of the patient's reaction to

awareness of minor degrees of cognitive impairment. This may call forth anxiety and depression, especially when the previous personality has been marked by traits of insecurity or feelings of personal inadequacy. Much will depend on the demands made by the environment, and on the handling which the patient receives during the early post-traumatic phase.

In other cases, however, circumscribed brain damage may operate more directly by disruption of cerebral systems upon which the synthesis of the personality depends. The latter situation is compatible with excellent preservation of intellect to formal testing, yet the personality change is nonetheless 'organic' in origin.

A 34-year-old man was referred for psychiatric rehabilitation 7 years after head injury. A fall at work had resulted in fractures of the frontal bones of the skull and these had opened up pathways of infection from the frontal sinuses to the brain. Over the ensuing years extensive chronic abscess formation had caused much brain destruction in both frontal lobes. Prior to the accident he had been a stable thoughtful man, happily married and interested in his family. Now he was talkative, restless and grossly disinhibited. His wife had divorced him on account of his preoccupation with pornographic material and his irresponsibility generally. Twelve thousand pounds

awarded to him by way of compensation had been spent within a few months, partly on extravagant presents for relatives and acquaintances, and partly on the reckless purchase of a business which soon went bankrupt. He showed no concern or insight into his disabilities, and made jocular comments about the troubles which had befallen him. Full psychometric testing showed a level of intelligence within the average range and consistent with his previous education and work record. No memory or learning deficits could be detected (Lishman 1973).

A 24-year-old guardsman shot himself through both frontal lobes while playing Russian roulette. He was in coma for 10 days, and mute, incontinent and profoundly anergic for many months thereafter. When seen 3 years later he was permanently hospitalised and appeared to have reached a plateau where improvement was concerned. Apart from dysarthria there were no neurological abnormalities. He was polite and friendly, and on first acquaintance there was little abnormal to detect. Conversation revealed a rather off-hand manner with some degree of euphoria, but he was reasonably well informed about current events. In his daily life, however, he was profoundly lacking in initiative and needed supervision to care for his appearance. When left to his own devices he preferred

to lie in bed for most of the day. He was inclined to indulge in childish pranks, and to buy pin-up magazines and talk of women though libido was totally lacking. He was extremely easily led into mischief and had twice been convicted for breaking and entering while on leave from hospital. The only change he recognised in himself was that nothing worried him any more. He showed no remorse about the recent convictions and no concern about his future. When asked about the game of Russian roulette he replied that it had been 'a bit silly, I suppose'. Psychological testing showed intelligence in the average to superior range with no disturbance of memory. But perseverative tendencies were marked and there was considerable difficulty in shifting attention from one task to another.

Though formal tests of intellect may be normal, patients with these sorts of personality change often do badly on tests of social cognition, decision-making and control of goal-directed behaviour. The cognitive impairment and personality change may be two sides of the same coin. This was proposed by Tate (1999) with respect to executive dysfunction and characterological change after head injury. She found greater loss of emotional control, a measure of characterological change, was predicted by more rule-breaking errors in a test of verbal fluency, a test of executive function.

It seems likely that damage to orbitofrontal or ventromedial frontal cortex is central to both the impairment of higher cognition (social cognition, decision-making and control of goal-directed behaviour) and the personality. Damasio (1996) uses a 'somatic marker' hypothesis to explain the link between damage to medial orbitofrontal lobe and impaired social decision-making. It is proposed that normal social behaviour depends on a somatic marker, linked to the limbic system, guiding social decisions based on experience of the outcome of previous similar situations. Decisions which in

the past have resulted in poor outcomes are suppressed by the somatic marker. This process is critically dependent on the medial orbitofrontal cortex, where limbic system responses, thought to underpin the somatic marker, are able to influence decisions that depend on cortical processing.

Damasio suggests that failure to recognise and understand emotional signals and social cues is not the problem. The problem lies in the ability to decide and act appropriately despite good social understanding. However, not all agree that social understanding is intact. Patients with ventromedial frontal lesions show impaired ability to interpret non-verbal emotional expression, e.g. from body posture or facial expression (Mah *et al.* 2005); this impairment correlated with greater scores on the Neurobehavioural Rating Scale. Similarly, impairments of recognition of expressions of emotion have been found in a patient with orbitofrontal injury and acquired sociopathy (Blair & Cipolotti 2000). Others have emphasised the role of ventral frontal cortex in the extinction of previously rewarded behaviour (Rolls *et al.* 1994). Patients with ventral frontal lesions, half of whom had suffered a head injury, were unable to alter their behaviour appropriately despite being aware that the situation had changed. Their scores on a questionnaire rating disinhibition or other socially inappropriate behaviours correlated with failure to switch responses.

Milders *et al.* (2003) were able to demonstrate that patients after head injury had problems recognising facial expressions and detecting social faux pas, but the impairment did not correlate with ratings of behavioural problems, although there were trends in the direction of greater impairment being associated with greater behavioural problems. Tests of gambling behaviour may weakly predict the failure of patients to regulate behaviour according to internal goals (Levine *et al.* 2005).

It therefore seems likely that the personality change many describe as the frontal lobe syndrome is due to subtle but disabling impairments of higher cognitive function, particularly as they relate to social understanding and decision-making especially in complex unstructured situations to meet internal goals.

Aggression

The symptom of reduced control over aggression deserves special consideration (see Chapter 2, Disordered control of aggression). This is seen with sufficient frequency after head injury, and often enough in relative isolation, to suggest a particular association with head injury. Three times as many head-injured patients showed significant aggression during the first 6 months post injury as did a control group with multiple trauma but without head injury (33.7% vs 11.5%) (Tateno *et al.* 2003). This difference was not explained by greater alcohol use or depression in the head injured. And problems with aggression continue for many years in a proportion of cases. Indeed relatives tend to report increasing problems with temper outbursts over the years post injury

(Brooks *et al.* 1986; Hall *et al.* 1994). Using a fairly conservative estimate of aggressive behaviour, measured using the Overt Aggression Scale (Yudofsky *et al.* 1986), about one-quarter of patients are found to display aggressive behaviour at 6, 24 and 60 months after discharge from an inpatient rehabilitation unit (Baguley *et al.* 2006). At each time point it was not simply the same patients who displayed aggression; a good proportion of patients moved from being aggressive to not aggressive and vice versa in no particular pattern.

It is customary to distinguish verbal aggression from physical aggression towards either objects or people. Though this is important for risk management, there is little evidence that these different behaviours can be teased apart. Agitation, on the other hand, with marked restlessness and distractibility, is usefully considered separately even though aggression may be present. Agitation is particularly likely to be seen in the early post-injury period in the context of the post-traumatic delirium. Sexually aggressive behaviour, often with evidence of other sexually disinhibited behaviour, may be seen in relative isolation from other forms of aggression and is considered in detail later in this chapter (see Sexuality, social adaptation and effects on the family).

Predictors of aggression include alcohol (Tateno *et al.* 2003), younger age at injury (Greve *et al.* 2001; Baguley *et al.* 2006), being depressed (Tateno *et al.* 2003; Jorge *et al.* 2004; Baguley *et al.* 2006), frontal injury (Tateno *et al.* 2003; and see discussion on frontal injury and personality change above), and a pre-injury history of antisocial behaviour (Greve *et al.* 2001; Tateno *et al.* 2003).

One question of interest is whether a particular pattern of aggressive behaviour tends to be seen in patients after TBI. Hooper *et al.* (1945) described 12 cases of 'episodic rage' with sudden explosions of violent behaviour under minor provocation, sometimes bringing the individuals before the courts repeatedly. The authors stressed that the condition was very different from the more common symptom of post-traumatic irritability, especially in its explosive quality. It could occur, moreover, without evidence of irritability between attacks. In general the problem was found to follow severe head injury, although in a few cases the blow had been quite mild. Such behaviour has been described as the *organic aggression syndrome* (Silver *et al.* 2005) (Box 4.3). The term 'episodic dys-control syndrome' has also been used (Eames & Wood 2003). In some patients small amounts of alcohol will trigger the attacks. Very occasionally it may represent an epileptic phenomenon. Short of this, EEG studies may reveal focal temporal lobe disturbance, and on theoretical grounds suspicion falls heavily on brain damage implicating the periamygdaloid region within the temporal lobes (Eames & Wood 2003). The argument that an epileptic disturbance may be involved is difficult to confirm but receives gentle support from the observation that carbamazepine may be effective.

However, good empirical evidence that brain injury does result in a specific syndrome of aggressive behaviour is

Box 4.3 Characteristic features of organic aggression syndrome (Silver *et al.* 2005)

- Reactive: triggered by modest or trivial stimuli
- Non-reflective: usually does not involve premeditation or planning
- Non-purposeful: aggression serves no obvious long-term aims or goals
- Explosive
- Periodic: long periods of relative calm
- Ego-dystonic: afterwards patients show remorse and are upset; behaviour is out of character; do not blame others or justify behaviour

lacking. Some clinicians would argue that in the majority of cases troublesome aggression is observed in those who were inclined to aggression before their injury, and in whom there is a background level of increased irritability, intolerance of frustration, and mood swings. There may well be alcohol and drug abuse in the background. Aggressive behaviour in such patients is sometimes a means to obtaining what they want, though at other times may serve no purpose. It seems likely that cases of aggression after head injury do not form a homogeneous group. Indeed, careful enquiry may show that aggressive outbursts have characterised the individual from childhood and adolescence onwards, and that the head injury is merely being blamed for a pre-existing condition (Lishman 1978).

However, other habitually aggressive persons may show true worsening. In some the explosive diathesis will have emerged as a new disorder, out of character for the individual and relevant directly to the injury. The more severe the injury, the more likely that brain damage is responsible. Frontal lobe damage may be particularly significant (Grafman *et al.* 1996) on account of its disinhibiting effects on the personality. One must remain alert, nonetheless, to the possibility that current life stresses, affective disorder or paranoid developments are the factors principally operating to aggravate the situation.

In many cases it is the family who are particularly at risk. In some cases this may be because of conspicuous jealousy within the marital context, or it may reflect high levels of expressed emotion. Burgess and Wood (1990) describe a patient whose uncontrollable behavioural outbursts could easily be triggered by the ward staff, but were immediately inhibited when the doctor appeared on the scene. They argued that this was because of a failure of contention scheduling by the patient. Once anger was triggered, the patient was unable to switch to a behavioural schema that was able to inhibit the anger. However, the appearance of the doctor, perhaps because of what he or she represented, caused automatic selection of a new behavioural schema and an end to the outburst.

Sometimes psychogenic factors may emerge in the end as playing the most important part.

A man of 21 had shown repeated episodes of markedly aggressive behaviour, chiefly directed towards the police, since a road traffic accident 2.5 years earlier. These had led to repeated convictions and several brief periods of imprisonment. He had previously been a police cadet and there was ample evidence that his conduct prior to the injury had been entirely satisfactory. Detailed investigations failed to show any evidence of brain damage; full EEG studies revealed no abnormality, psychological testing indicated good intelligence without evidence of intellectual impairment, and prolonged fasting showed no evidence of hypoglycaemia. The injury itself had been mild, without neurological sequelae and with a PTA of only 20 minutes.

The great majority of aggressive outbursts occurred after excessive drinking, and when the patient felt that he had been provoked in some degree. Excessive drinking had set in during a phase of severe depression following the loss of a friend in the accident, and continued as the patient became progressively embittered and disgruntled at his failure to find a new career. He now found himself in a vicious circle as a result of repeated convictions, and much of his aggressive behaviour could be seen as bravado in attempts to regain his self-esteem. His hatred of the police force was overt, and he felt their rejection keenly. When drunk, encounters with the police led immediately to the release of explosive outbursts of violence.

Studies of violent offenders have also demonstrated the link between aggression and head injury. For example, moderate to severe head injury was found in 6 of 20 men convicted of domestic violence compared with only one of 20 controls (Turkstra *et al.* 2003). Others have found associations with crime in general. High rates of reported head injury, antedating their forensic history, have been found in convicted felons (Sarapata *et al.* 1998). Men who have committed murder before age 18 are very likely to have suffered a serious head injury in childhood (Lewis *et al.* 2004). One study identified 152 men who had suffered a head injury before age 15 from a prospective study of 12 000 born in Finland in 1966. These men had an increased risk of being in the national register for criminal offences committed after age 15 (OR 1.6); in about 30% of cases this was associated with alcohol abuse (Timonen, Miettunen *et al.* 2002). In the majority of cases the head injury was probably mild, being defined as 'concussion', i.e. without evidence of contusion or skull fracture. This suggests that at least part of the association between suffering a head injury and engaging in a criminal career was because of personality characteristics that are risk factors for both. In other words those who are likely to lead antisocial

lives are also likely to suffer a head injury as a child or adolescent.

Personality change without brain damage

Changes of temperament less likely to be based on brain pathology include fluctuating depression, morbid anxiety, obsessional traits and persistent irritability. All are common, and frequently come to be included under the rubric of personality change. Often they represent an intensification of previous personality traits and will have emerged on other occasions under different conditions of stress. They may emerge as responses to physical defects or minor cognitive impairments, certainly in the early stages of convalescence, but when persistent they can more commonly be traced to stresses consequent upon the injury. They are, in fact, often more accurately to be regarded as neurotic reactions than as changes of personality. In some cases detailed enquiry will show that they conform to the picture of post-traumatic stress disorder (PTSD), with intrusive thoughts concerning the accident and avoidance of situations related to it. PTSD can be long-lasting as a source of chronic disability, with reports of it persisting even several decades after wartime stresses. Such patients may readily come to be labelled as suffering from personality change.

Psychoses

The psychosis that can occur during the period of acute post-traumatic delirium has already been described. Psychotic episodes may develop later in association with post-traumatic epilepsy, and here also an organic basis can be discerned. The problem is more complex when chronic psychoses, of a schizophreniform or affective nature, develop in a patient whose head has been injured. The causal role of the injury may then be far from clear, especially if some considerable time has elapsed between the trauma and the onset of the illness. Frequently the patient or his relatives will seize upon the injury in retrospect as an acceptable and understandable cause, and the issue may become a matter of medico-legal importance.

Various possibilities exist. Brain disturbance may itself contribute directly to such developments; or the injury may have acted as a non-specific stress to precipitate the psychosis. Alternatively, factors associated with the psychotic illness caused the head injury (reverse causality). For example, the head injury occurred during the prodromal phase of the psychosis, or personality characteristics which increase the risk of psychosis also increase the risk of suffering a head injury. Finally, of course, the possibility of simple coincidence must also be considered.

These matters have not been disentangled to a satisfactory extent and the rigorous review of David and Prince (2005) lays out the complex issues. Large numbers of cases are hard to assemble, and comparisons between different series raise

special difficulties, not least with regard to diagnostic criteria. In general, the longer the lapse of time between the injury and the onset of the psychosis, the more likely that the relationship is coincidental. However, even with a lapse of many years it can be very difficult to discount the injury entirely as a contributory factor, especially if there is clear evidence of persisting brain damage with symptoms derived therefrom in the interim. Both organic disturbances and psychological aftermaths can sometimes be expected to operate over long periods of time in contributing to psychotic developments, for example the long interval characteristically observed between the onset of epilepsy and the onset of the schizophrenia-like psychoses related to it (see Chapter 6).

Nevertheless, a constitutional predisposition to the psychosis is probably a major factor in many cases of psychotic illness following head injury. Tennent (1937) found evidence of special vulnerability in five cases of schizophrenia where the psychotic illness followed directly on the head injury and became manifest as soon as the delirium subsided. All had shown evidence of schizoid traits in the premorbid personality, and the illnesses followed the course of ordinary schizophrenia. Among four depressive psychoses, three had been treated previously for similar affective disorder. The injuries therefore appeared to have made manifest, at a particular point in time, what would in all probability have followed other stressful situations in that particular person.

What is the evidence that head injury can cause a chronic psychotic illness, a schizophrenia or schizophreniform psychosis, not secondary to hypomania or depression? Sometimes in a particular patient it is difficult to refute the argument that had he not suffered the head injury he would not have become psychotic. The argument tends to rest heavily on the observation that the psychotic illness appears to have evolved from symptoms that were seen in the post-traumatic delirium, particularly confabulations or perceptual distortions. Delusional misidentification may be a central feature of the psychosis in these patients (Marshall *et al.* 1995). Delusional misidentification, for example reduplicative paramnesia, is characteristic of the post-traumatic amnesic period but in rare cases can extend beyond this period and last for several years. Derealisation may play a part and Young *et al.* (1992) describe a case where derealisation seemed to play a part in the development of Cotard's syndrome, as it did in the following case.

Four years earlier, a 33-year-old man had suffered a very severe head injury requiring over 6 months inpatient treatment and rehabilitation. A sense of derealisation began within a few months of the accident. Initially it was intermittent and cyclical but in the past 2 years had become constant. He found it impossible to accept the world was real, instead believing that he had died and was living in the

'afterlife'. He believed that people he knew, in particular his wife, had been replaced by imposters using the 'shells' of his previous family and friends. Minor happenings would support his conviction, for example an error in a newspaper article 'would not have happened in the real world'. The beliefs were very distressing and he had almost no insight into them. He became rigid, irritable, cold and aloof and unable to manage the family finances. At times he had become depressed and suicidal and had attempted to harm himself on two occasions. MRI (Fig. 4.8) showed ventriculomegaly with atrophy of the corpus callosum and evidence of old haemorrhage into the cerebral white matter, findings consistent with diffuse axonal injury.

Another example of the phenomenology of the psychosis supporting the notion that the psychosis is a direct consequence of the head injury is to be found in patients with severe cognitive impairment with amnesia and poor insight. Some of these patients may show persecutory delusions centred on the belief that belongings of theirs have been stolen; such delusions are typical of, for example, Alzheimer's dementia. It is also of interest to consider whether patients who are psychotic after head injury have special characteristics. On the one hand, are they different from psychotic patients without a head injury? On the other, are they different in some way from head-injured patients who are not psychotic?

There have been two case-control studies comparing head-injured patients with chronic psychosis with head-injured control (non-psychotic) patients to see if there is anything particular about head-injured patients who develop psychosis. Sachdev *et al.* (2001) ensured that the controls were age and sex matched to the psychotic patients, but ascertainment bias and relatively small numbers limit con-

fidence in the findings in both studies. Moreover, given their methodology neither study allows any direct conclusion as to whether psychosis is more common after head injury. One-third of the patients of Fuji and Ahmed (2001) were taking illicit drugs that might induce psychosis, compared with about 10% of those without psychosis. Both studies found that, unlike those without psychosis, more than half of psychotic patients were below the age of 21 when injured. The mean interval between injury and psychosis was about 4–5 years. Epilepsy was if anything more frequent in the non-psychotic patients. The vast majority of the Fuji and Ahmed (2001) series suffered mild head injury, and this was less severe than in controls, whereas in the Sachdev *et al.* (2001) series more severe injury was observed in those who were psychotic. Sachdev *et al.* found higher rates of family history of psychosis in a first-degree relative in the psychotic group, confirming this as one of the best-established risk factors for the development of psychosis after head injury (Achté *et al.* 1969; Davison & Bagley 1969). Both studies considered whether the chronic psychosis they observed in these head-injured patients differed from that seen in patients with schizophrenia, and suggested there was less evidence of negative symptoms in those with psychosis following head injury. However, no telling differences were seen.

More convincing evidence that rates of chronic psychosis may be increased after head injury comes from the study of cohorts of head-injured patients that have been followed up. These are usefully reviewed in David and Prince (2005). Many of the studies come from series of soldiers with open head injuries and using criteria for psychosis that are difficult to interpret. Achté *et al.* (1967, 1969) produced one of the most comprehensive studies of psychotic illness after head injury by following 3552 Finnish soldiers who fought in the Second World War for 22–26 years; the majority had suffered closed head injury, although injury was often due to shrapnel. During this period 92 patients (2.6%) developed

Fig. 4.8 A 33-year-old man with 10 days loss of consciousness after head injury left him with mild to moderate cognitive impairment. Some months after the injury he developed the belief that his wife had been replaced by an imposter and that the whole world was unreal and that he was dead. (a) Coronal section T1 weighted MRI shows mild ventriculomegaly and atrophy of corpus callosum and hippocampi. (b) Gradient-echo axial MRI shows old small haemorrhages in frontal lobes.

psychoses resembling schizophrenia, which is well above the incidence to be expected in the general population. They found that patients with mild injuries developed schizophrenia more frequently than those with severe injuries, and suggested that factors independent of the injury usually played a decisive role.

Civilian cohorts tend to be smaller and unfortunately, though they hint at increased rates of chronic psychosis, many are also jeopardised by poor definition of psychosis. Roberts (1979) described seven cases of paranoid dementia plus two with a schizophrenia-like psychosis developing 10–24 years after severe head injury in 291 civilian patients, suggesting a fivefold relative risk compared to those without a head injury. The findings of De Mol *et al.* (1987), suggesting a threefold to fourfold relative risk are not easy to interpret given that in 80% the psychosis occurred within 6 months of the injury. Two smaller studies are of potential interest. Thomsen (1984), a speech pathologist, describes eight cases of ‘post-traumatic psychosis’ in 40 patients with very severe head injury followed up over 10–15 years; these eight cases tended to be younger, with no patient over 25 and five in their teens when they suffered the head injury. Unfortunately, from the description of the cases it is not clear that they were in fact suffering with psychotic symptoms, for example two patients were sexually disinhibited and fits of rage attacks were seen in three, but there is no description of the patients suffering delusions or hallucinations. Lezak (1987) describes eight patients, from a cohort of 42 men with very severe head injury (the majority had loss of consciousness of more than 2 weeks) followed up every year for about 5 years, who on at least three occasions displayed hallucinatory or delusional ideation, paranoia or both. None had any prior psychiatric history. In their study of psychiatric illness 1 year after a head injury, the majority being mild, Deb *et al.* (1999b) found one patient to have developed schizophrenia, equivalent to an annual incidence of 0.8%, more than would have been expected in the normal population. Koponen *et al.* (2002) in their study of 60 patients followed up 30 years after injury found psychotic disorder with onset after TBI in four male patients (6.7%; CI 1.9–16). Two of them had moderate brain injuries and the other two severe. Three of the four had delusional disorder and two also had dementia. In two cases the onset was within 1 year of injury but in the other two delusional disorder did not appear until 10 years post injury.

It is therefore difficult to draw any consistent conclusions from these cohort studies. There is an impression that younger patients at the time of injury are more vulnerable to developing psychosis, though of course it is people in their late teens and early twenties who are most vulnerable to developing schizophrenia anyway. Many of the studies hint at an increased rate of psychosis compared with the normal population and this is not far different from Davison and Bagley’s (1969) estimate of a twofold to threefold relative risk. However, for many studies the numbers are small and

the confidence intervals large and the definition of what constitutes a psychotic illness is weak. They rely on independent assessment of rates of psychosis in the normal population to draw any conclusions about the relative risk.

Large surveys of the total population, including all those who are or are not psychotic and who have or have not had a head injury, do allow direct assessment of the relative risk of head injury in those who develop psychosis. One such cross-sectional survey is the National Epidemiologic Catchment Area Study in the USA. Silver *et al.* (2001) analysed the survey data and found that 361 of 5034 participants indicated that they had suffered a head injury causing loss of consciousness or confusion; 73 of the total sample developed schizophrenia, 3.4% of the head-injured group and 1.9% of those without a head injury (after adjusting for several variables including age, sex and alcohol abuse). The OR of 1.8, controlling for age, sex, marital status and socioeconomic status, was just significant, indicating almost twice the rate of schizophrenia in those with a history of head injury. However, the OR was no longer significant after also adjusting for alcohol use (OR 1.7, CI 0.9–3.0). In summary the study suggests there may be a less than twofold increase in the rate of schizophrenia.

Case-control studies also allow direct comparison of the association between head injury and psychosis. The standard retrospective case-control takes patients who have developed psychosis and asks them if they have ever suffered a head injury to see if there is an excess rate in those who are psychotic compared with controls. Two studies have examined this in terms of childhood head injury as a risk factor for later schizophrenia. One looked at this question from the point of view of childhood head injury in those admitted to hospital with mental illness or for surgery (Wilcox & Nasrallah 1987). Compared with surgical controls, those admitted with schizophrenia had a much higher, and statistically significant, rate of reported head injury in childhood (OR 16). This was greater than for those with bipolar disorder (OR 7), although given the large confidence intervals this was not statistically significant. Recall bias could have had a marked effect in this study, weakening one’s confidence in the conclusion. AbdelMalik *et al.* (2003) used unaffected family members ($N = 102$), from 23 families in whom more than one had schizophrenia, as controls. In these multiply affected families, 16 of 67 who suffered schizophrenia reported having had a head injury before age 11 compared with 12 of 102 unaffected controls. The OR of 2.3 was just significant. However, in almost all cases the head injury was mild, of whom probably a good proportion suffered no loss of consciousness.

Another study that used unaffected family members from schizophrenia pedigrees as controls is the case-control study of Malaspina *et al.* (2001). Subjects from families in whom at least two members had schizophrenia or two members had bipolar disorder were asked whether they had ever had a head injury. The controls were the unaffected family

members. Those with schizophrenia reported having had more head injuries than the unaffected family members (OR 3.3) and this was slightly, but not statistically significantly, more than for bipolar disorder (OR 2.2). Those who came from a schizophrenia pedigree and suffered a head injury were more likely to develop schizophrenia than bipolar disorder, whereas this was not the case with bipolar disorder; there may be a pathoplastic effect of familial predisposition to schizophrenia on the outcome of head injury. Of particular interest was the finding that those at risk of developing schizophrenia have a greater risk of suffering a head injury.

The case-control studies described thus far have all relied on retrospective reporting of a history of head injury. More recent studies have used large databases of health records to enable direct comparison between those recorded, at the time, as being admitted with a head injury and subsequently recorded as suffering a psychotic illness. Fann *et al.* (2004) interrogated the records of a health maintenance organisation covering 450 000 people in Washington state. Every person aged 15 or older with a head injury in 1993, diagnosed using ICD coding in the emergency department or inpatient wards or outpatient clinic ($N = 939$ of whom 136 were moderate/severe), was tracked to see whether they developed a psychiatric illness in the 3 years following the injury (classified either by diagnosis or antipsychotic use). The psychiatric health of the subjects during the year before the head injury was also assessed. For each person, three age- and sex-matched controls without head injury were likewise followed up. In those without a preceding history of psychosis, and with a moderate to severe head injury, in the second and third years post injury there was an elevated risk of psychosis (OR 5.9 and 3.6 respectively, both just statistically significant). However, the interpretation of this finding is not straightforward. It is based on small numbers, so the confidence intervals are large. The majority of those with moderate and severe head injuries were over 65. It seems that merely being prescribed an antipsychotic was sufficient for a person to be labelled as suffering a psychotic illness. And as David and Prince (2005) point out, those subjects with apparent new-onset psychosis in the 3 years post injury may well have had a history of psychosis in the more distant past. In fact the most striking finding from analysis of this database is that having a mental illness makes a person at increased risk of suffering a head injury within 1 year (Fann *et al.* 2002).

Nielsen *et al.* (2002) used the Danish national health record databases. In this study the cases studied were 8288 patients having their first admission for schizophrenia. They were compared with 82 880 age- and sex-matched controls without schizophrenia. The register of all admissions to Danish general hospitals was then searched to see if these cases and controls had suffered a head injury requiring admission to hospital in the 15 years before the admission for schizophrenia (or in the case of controls an equivalent risk period). To try to control for accident proneness, the database was also

searched to see if the subjects had been admitted for a fracture but without head injury. Compared with controls, patients with schizophrenia were not at increased risk of head injury. For example, 2.2% of patients with schizophrenia compared with 2.4% of controls had suffered a 'severe' head injury in the at-risk period. Closer analysis of the data did suggest that in men there was a relative excess of head injury compared with fractures, but it is difficult to interpret exactly what this finding means. The effect was greatest in the year before diagnosis of schizophrenia; this was the time the patients seemed to be at greatest risk, over and above controls, of suffering a head injury. This is compatible with reverse causality; during the prodrome of the schizophrenia the risk of head injury is increased. However, this explanation does not sit comfortably with the observation that risk of fractures was not increased in the year before schizophrenia. The study design was limited by the ascertainment method to determine schizophrenia; patients had to have been both admitted to hospital and given an ICD-8 diagnosis of schizophrenia. Nevertheless, it can be argued that a patient who is significantly disabled after a head injury, compared with a previously fit person, is likely to take a different pathway to care when becoming psychotic for the first time. These patients might also be expected to be diagnosed with an organic psychosis rather than schizophrenia. Both effects could result in underreporting of the number of patients who develop a non-affective psychosis after a head injury. And these effects would be most evident in those with the severest injuries, perhaps those most at risk of developing a psychotic illness. More recently, Harrison *et al.* (2006) using similar methods found no excess risk of schizophrenia after head injury, but did find a small increased risk of non-schizophrenic non-affective psychoses (OR 1.37). This finding is compatible with the argument that there is a slight increased risk of non-affective psychoses after head injury.

From this review of the evidence it can be seen that it is not possible to come to any definite conclusion about whether head injury can cause a chronic psychotic illness, a schizophrenia or schizophreniform psychosis, not secondary to hypomania or depression. Nevertheless, across a range of study designs there is a fairly consistent message that there may be an increased risk of schizophrenia-like illness after head injury. However, in many of these studies the head injury was mild, probably making the studies more vulnerable to spurious reporting and ascertainment effects, and also hinting that the head injury was acting as a non-specific psychological stressor, rather than brain injury explaining the link. Two other conclusions emerge from the review. First, those with a predisposition to psychosis are at greatest risk of developing psychosis after head injury. This suggests that those who develop psychosis after head injury might well have become psychotic even if they had not been injured. Second, those at risk of developing a psychotic illness are probably also at greater risk of suffering a head injury, an

example of reverse causality. Some will suggest that the methods and size of Nielsen *et al.*'s (2002) study trump all others and that this study is the only one to trust. Others will suggest that though large and apparently robust, even this study is open to question, and that a reasonable conclusion to draw is that head injury does increase the risk of psychosis, perhaps doubling it. Nevertheless, probably the majority of those who become psychotic after head injury, particularly if it is a mild head injury, would have developed a chronic psychosis anyway. Furthermore, it is quite likely that in fact these patients only had a head injury in the first place because their predisposition to psychosis was associated with being accident prone. Given this tentative conclusion that head injury causes chronic psychosis, more specific conclusions, for example that psychosis is especially linked to temporal lobe damage (Davison & Bagley 1969), must be regarded as somewhat speculative.

Another question of interest is the effect of head injury on the course of schizophrenia. It is not uncommon for patients with schizophrenia to suffer a head injury, either accidental or due to deliberate self-injury. Is this likely to make their psychotic illness worse? Or will the head injury aggravate the negative symptoms of schizophrenia? At present there is no evidence to answer these questions. Of interest is the case report of Pang and Lewis (1996) suggesting that damage to the left prefrontal and temporal cortex following a head injury changed the pattern of symptoms in an individual with past history of bipolar affective disorder, such that the patient developed typical schizophrenia 9 months later.

Mood and anxiety disorders

Mood disorders (affective disorders) following TBI are an important focus for diagnosis and treatment (Evans & Levine 2002; Fleminger *et al.* 2003b). However, two important questions about the nosological status of these disorders in somebody with a brain injury emerge (Eames 2001). First, to what extent should emotional reactions that are easily understandable in terms of the adverse effects of the injury on the person be diagnosed as depression? Second, what is one to make of symptoms of mood disorders, for example anhedonia and apathy, when these symptoms may also be a direct consequence of brain injury? Frontal lobe injury may produce states where fatuous jocularity is prominent, not dissimilar to changes sometimes seen in hypomania. Bilateral high brainstem or internal capsule lesions may produce the syndrome of pseudobulbar palsy, with dramatic brief-lived pathological laughter and crying. Is this a disorder of the affect such that the patient feels like laughing or feels sad, or a disorder of the expression of emotion but in the absence of any subjective change in affect? On the other hand, it is quite possible, particularly in those with severe injury, that any subjective mood state is masked because the patient lacks the ability to express feelings.

For these reasons standard diagnostic schema, like the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), should be interpreted with care when applied to the brain-injured person. This is particularly the case if information is collected by self-report in response to standard questions, rather than by interview with somebody familiar with psychiatric diagnosis. Rating scales, like the Hamilton Rating Scale or the Beck Depression Inventory or Hospital Anxiety and Depression Scale, are even less reliable ways to identify clinical syndromes. Such methods will fail to distinguish symptoms like concentration impairment that may be a direct consequence of brain injury from bona fide symptoms of a depressive illness. The typical emotional sequelae of head injury overlap with changes of personality, including moodiness and dysthymia, and normal reactions to life events. Symptoms of anxiety are often prominent. Symptoms such as feeling miserable, powerless, frustrated and dissatisfied, being irritable and moody do not sit happily in any nosology. The propensity for individual clinicians to rate such symptoms as evidence of a mental illness probably varies markedly, and this may partly explain the large differences in reported rates of depression following head injury.

Bipolar affective disorder including manic-depressive psychosis and mania

Psychotic symptoms associated with mood disorders

Chronic psychotic illness not secondary to hypomania or depression has already been discussed. An early suggestion that head injury can result in a psychosis associated with a mood disorder came from Symonds' (1937) description of two patients with depressive psychosis in whom the symptoms developed before they had recovered from their acute post-traumatic confusion. Symonds proposed that as the patients could not appreciate the effects of the injury at the time, this was evidence favouring the view that the illness was the direct result of organic brain disturbance.

Occasional case reports of psychosis associated with mood disorder are to be found (McLay *et al.* 2004), sometimes associated with nihilistic delusions related to a sense of derealisation (Butler 2000) (see Fig. 4.8). On the other hand, Hibbard *et al.* (1998) found 23% of those diagnosed with major depression after head injury to have psychotic symptoms. This was based on a survey of 100 community-dwelling patients at least 1 year, and on average 7 years, after a head injury; 61% were identified, using a structured interview by a psychologist, to have major depression. Given this very high rate of depression, the finding that about 12 of the 100 patients had psychotic features should be interpreted with caution.

Bipolar affective disorder

Mania may occur early after head injury. In one study of six patients who developed mania (9% of all cases with a head injury), all but one had resolved by 6 months post injury

(Jorge *et al.* 1993a). However, symptoms of mania will overlap with symptoms typically seen in the period of PTA, when agitation, distractibility, irritability and disinhibition are common, and this may lead to diagnostic confusion. An example of this diagnostic dilemma is to be found in the case report of Mustafa *et al.* (2005) of a woman developing increased psychomotor activity and decreased need for sleep 23 days after a head injury and almost certainly in the period of PTA. Mania developing later after injury is relatively uncommon and point prevalence studies, for example at 1 year (Deb *et al.* 1999b), may fail to identify any patients who are manic. Ach   *et al.* (1967) found 47 cases of affective disorder (1.3% of their series) of whom only three were typically manic–depressive. Mortensen *et al.* (2003) used a case–control methodology to interrogate the Danish medical and psychiatric databases to see whether head injury was a risk factor for later bipolar affective disorder. Those with bipolar affective disorder were 1.5 times as likely to have suffered a previous head injury requiring admission. The increased risk was confined to head injury occurring within 5 years of the bipolar illness and only accounted for a small proportion of bipolar disorder.

Much of the literature has tended to rely on case studies. Bracken (1987) found 20 cases in the literature and reported a striking example of his own as follows.

A 48-year-old woman fell from a trapeze sustaining multiple injuries. She lost consciousness for 10 minutes and had a PTA of approximately 3 days. On recovery from her physical injuries she was confused and disorientated, and over the next few days became overactive and grandiose. This was 3 weeks after her fall. The CT scan was normal. On transfer to a psychiatric unit she was fully orientated but with marked pressure of speech and flight of ideas. She reported feeling very happy and ‘very strong’ and said she was writing a book which would be a best seller. There was no previous personal or family history of psychiatric disorder.

With chlorpromazine and haloperidol she gradually settled over the next 8 weeks. She then developed a depressive episode which responded to mianserin. Psychological tests suggested possible residual deficits in visual and verbal memory, and there was persistent diplopia due to fourth cranial nerve palsies. She was well again 3 months after the accident.

Clark and Davison (1987) reported two further cases, one beginning 2 months after closed head injury and the other 6 months after operation for post-traumatic subdural haematomas. Shukla *et al.* (1987) assembled 20 cases, the mania following closed head injury by a mean of 2.8 years (range

0–12 years). No patient had a family history of bipolar illness, though six had one or more relatives with histories of depression. Epilepsy had developed in half of the patients and appeared to be a predisposing factor. Among phenomenological features, they stressed that irritable moods were commoner than euphoria and that assaultive behaviour was common. Fourteen patients experienced recurrent mania without depression, and the sample as a whole showed an excess of manic over depressive episodes.

A study of 12 patients who developed mania after a variety of brain lesions (tumours, strokes and head injuries) was presented by Starkstein *et al.* (1988). Of the two head injuries in the series, one developed repeated manic episodes after an interval of 18 months, and the other became manic 2 years after frontal injury associated with marked change of personality. There have been a few case reports of rapid cycling manic–depressive illness developing after head injury (Zwil *et al.* 1993; Monji *et al.* 1999; Murai & Fujimoto 2003).

Although a story has emerged that secondary mania is more common with brain lesions involving the right hemisphere, there is little convincing evidence of any laterality effect after head injury. Mania is probably more common in those who have suffered head injury with damage to frontal, particularly orbitofrontal, and temporal cortex. Hoheisel and Walch (1952) suggested that hypothalamic damage might also play a part.

Major depression

Major depression is quite common after head injury, and remains so for many years after injury. Perhaps the first study to use standard criteria to diagnose depression was that of Jorge *et al.* (1993b) who found that major depression seen shortly after head injury may owe something to lesion location, whereas later-onset depression, nevertheless in the first year post injury, was more closely tied to psychosocial factors.

Of 66 consecutive patients admitted to hospital with closed head injury, 17 (26%) met DSM-III criteria for major depression at examination 1 month later. When compared with non-depressed patients they showed an increased past history of psychiatric disorder and a higher frequency of alcohol or drug abuse. Severity of injury was not significantly different, but analysis of lesion location from CT scans showed an excess of left anterior brain damage in the depressed group. Of those who were not depressed at 1 month, 27% went on to become depressed at 3, 6 or 12 months. At any one time, about 20–25% of patients were depressed, with over 40% of the cohort suffering depression at some point over the first year. Direct comparisons between early and later-onset depression groups confirmed the importance of lesion location in the former (frequently subcortical involvement) and of poorer social functioning in the latter.

Depression is found to be quite mobile in the first year after head injury. Those who are depressed often recover within a few months, and their place in the group found to be

depressed at a later time will have been taken by a patient not previously depressed. Thus less than one-fifth of those depressed at 12 months had been depressed at 1 month, and of those not depressed at 1 year almost half had been depressed at some stage earlier in the year. Other studies also find rates of clinically diagnosed depression of the order of 20–30% over the first year (Kersel *et al.* 2001; Jorge *et al.* 2004). Bowen *et al.* (1999) used a self-report measure to identify clinically significant mood disorders and found higher rates (39% at 6 months and 35% at 1 year). Deb *et al.* (1999b) offer a more conservative estimate for the rate of major depression observed at 1 year. Patients were interviewed by a psychiatrist using a standardised structured interview; 14% met ICD-10 criteria for major depression. When comparisons have been made, depression after head injury seems to be more common than in other patients without central nervous system involvement but with comparable injury or disability.

Longer-term prevalence studies suggest even higher rates of depression. Two studies from Kreutzer and colleagues, using different cohorts, find similar rates of depression. Their earlier study (Kreutzer *et al.* 2001) took 722 patients referred for outpatient assessment at a regional trauma centre on average 2.5 years post injury. Using items from a self-report measure that were regarded as diagnostically relevant to a DSM, they diagnosed 42% as suffering major depression. The second study (Seel *et al.* 2003) took 666 patients admitted for rehabilitation across several centres who were followed up. Using the same technique as in their first study, 27% met criteria for major depression. Hibbard *et al.* (1998) (see above) offer higher rates of depression. Hoofien *et al.* (2001) only studied patients with severe injury and found 45% to be depressed 14 years after injury. Rather similar figures are emerging for the rates of depression more than two decades after injury. Major depression was present in 27% of those injured 30 years before (Koponen *et al.* 2002). However, more conservative estimates were found by Holsinger *et al.* (2002) studying veterans of the Second World War 50 years after closed head injury and compared with men without head injury. The lifetime prevalence of depression was 18.5% compared with 13.4% for the controls.

These large variations in prevalence of depression some time after head injury may partly reflect the different psychosocial circumstances of the cohorts. There is an impression that later depression is more related to psychosocial adversity (Seel *et al.* 2003) and worse psychosocial outcome (Hibbard *et al.* 2004). On the other hand, selective ascertainment might partly explain some of the excess in depression; it is those patients who are depressed who are most likely to be referred for rehabilitation some time after injury.

One question of theoretical interest is the extent to which the depression seen in a person with a head injury is different in terms of phenomenology from depression in the absence of head injury. Aloia *et al.* (1995) found little difference between the two depression syndromes. Nevertheless,

apathy is probably more evident in depressed head-injured patients, Kant *et al.* (1998a) finding that 60% of their cohort of 83 head-injured patients were both depressed and apathetic; 20% had either apathy or depression alone and less than 20% were spared. A question of more practical interest given the potential difficulties diagnosing depression in somebody with a head injury is which symptoms best differentiate those who are depressed after a head injury from those who are not. Kreutzer *et al.* (2001) found that the most frequently endorsed symptoms of depression were fatigue (46%), frustration (41%) and poor concentration (38%), but these would be common in patients not depressed after a head injury. The best discriminators of those who are depressed from those who are not are probably symptoms such as lack of confidence, feelings of hopelessness, and self-deprecation (Jorge *et al.* 1993c). Biological symptoms, such as sleep disturbance, were not of much value early post injury. In fact sleep disturbance is common after head injury, regardless of depression. For example, 30% of patients attending a rehabilitation centre have been found to have insomnia, particularly problems with getting off to sleep (Fichtenberg *et al.* 2002). Hypopituitarism may contribute to depressive symptoms (Ghigo *et al.* 2005). Several studies have shown that depression is associated with anxiety, aggression and alcohol and substance abuse. It is more common in those with a history of affective disorder (Jorge *et al.* 2004; Rapoport *et al.* 2005).

After a severe injury patients often become increasingly aware of their disability as they recover, i.e. their insight improves. This may be one reason why patients seen after 6 months post injury demonstrate greater emotional reactions than do those seen within 6 months (Fordyce *et al.* 1983). As insight improves, depression increases (Morton & Wehman 1995). In a longitudinal study, Godfrey *et al.* (1993) found that improved insight into behavioural and cognitive impairments was associated with onset of emotional dysfunction. Wallace and Bogner (2000) used a cross-sectional approach. Patients on average 2 years post injury who lacked insight into their impairments were less likely to report anxiety and depression. These effects might partly reflect the observation in those without a head injury for depressed mood to be associated with better insight ('sadder but wiser').

A related question is the extent to which depressed mood can exacerbate cognitive impairment. This was studied by Rapoport *et al.* (2005) in 74 patients attending an outpatient TBI clinic many months following mild and moderate injury; 28% were diagnosed, using the Structured Clinical Interview for Depression, to have major depression. Controlling for effects of age and injury severity, these 21 patients showed greater cognitive impairment, particularly in terms of processing speed, working memory and verbal memory and executive function. For example, mean processing speed on WAIS was reduced from 19 to 14; the depressed patients made twice as many perseverative errors on WCST. A second study found that subjective memory complaints were more

likely in those who were depressed, and those with milder head injuries (Chamelian & Feinstein 2006).

Major depression is probably more common in those with pathological laughing or crying, otherwise called emotional lability or incontinence, or pseudobulbar affect. Pathological laughing or crying occurs in perhaps 5% of patients with head injury, and is associated with more severe injuries especially if there are neurological features of brainstem injury (Zeilig *et al.* 1996).

Mixed states of depression and anxiety

Post-traumatic states with mixed anxiety and depression represent the commonest of the psychiatric sequelae of head injury, in some series outnumbering all other forms of disability together (Ota 1969; Morton & Wehman 1995). Minor depression and states of tension and anxiety are frequently accompanied by irritability, phobic symptomatology and social avoidance. Biological features, for example anorexia, insomnia and early-morning waking, are rarely marked. The depression often fluctuates in severity, and may be responsive to change of activity and surroundings. Sometimes it proves to be no more than a readiness to be cast down by the troubles of daily life, and sometimes it is more accurately described as a state of gloomy and morose preoccupation. Symptoms of an anxiety disorder, in particular agoraphobia, travel phobia or PTSD, are common and sometimes the anxiety disorder is the outstanding problem (see below). When anxiety and depression are accompanied by somatic symptoms, particularly fatigue, headache, sensitivity to noise and dizziness, then the condition may be labelled post-concussion syndrome (see Post-concussion syndrome, later in chapter). Somatic symptoms are frequently the subject of anxious introspection and hypochondriacal concern.

Irritability is among the most common of the emotional consequences of injury and shows strong associations with depression and anxiety. The patient is more short-tempered than usual, more inclined to be snappy and stricter in matters of discipline. High levels of irritability persist for many years after injury (Brooks *et al.* 1986). All grades are seen, extending to the serious loss of control of aggression already considered above. It can be difficult to decide how far this represents an affective disturbance, or alternatively a personality change due to brain damage. Among patients with severe irritability persisting more than 1 year after injury, Lishman (1968) found little evidence to suggest that brain damage was an important factor in the group as a whole.

The failure of some classificatory systems, such as DSM-IV, to include a state of mixed anxiety and depression, or cothymia as it has been called (Tyrer *et al.* 2001), in their classificatory systems probably explains why recent studies using formal psychiatric classification may be a little misleading. A state of mixed anxiety and depression is rarely diagnosed, although authors may refer to a 'dual diagnosis'

or 'comorbidity' of an anxiety disorder and a depressive disorder.

Methods of assessment which use symptom questionnaires are probably better at capturing the spectrum of emotional reactions after head injury. For example, Fordyce *et al.* (1983) used the MMPI and the Katz Adjustments Scale (KAS) to identify the enhanced emotional reactions of head-injured patients. Those more than 6 months post injury were more anxious and depressed and more socially withdrawn. Curran *et al.* (2000) found that the presence of anxiety, measured using the State-Trait Anxiety Inventory (Spielberger 1983), was strongly correlated with the presence of depressive symptoms measured using the Beck Depression Inventory (Pearson's $r = 0.75$). Symptoms of anxiety and depression were more strongly associated with coping style than with severity or even the presence of brain injury. Those who dealt with problems in an active manner had fewer symptoms than those with a non-productive coping style characterised by, for example, self-blame and ignoring problems. Morris *et al.* (2005) used qualitative research methods to explore the content of symptoms of anxiety and depression after head injury. They identified some concerns that are often overlooked. For example, in some patients social anxiety was related to feelings of self-consciousness because of scars. Many suffered a persisting sense of loss due to failure to fulfil their dreams. Some described negative reactions from others. Often these were felt to be due to a lack of understanding of the consequences of head injury. Other participants mentioned feeling ignored or overlooked by others or feeling patronised.

Constitutional factors may be important in some cases. Neurotic reactions like those just described are probably more likely to occur in those prone to develop these symptoms anyway (see section on pre-traumatic factors above). The range of symptoms in a series of cases diagnosed as 'neurotics' (Slater 1943) was very similar regardless of whether the cohorts had suffered a head injury or not, as was the degree of vulnerability as judged by family and personal history. Nevertheless, Slater's study of soldiers subject to breakdown in war appeared to indicate that organic factors did play some part, although such factors are probably less important in those who develop chronic symptoms.

Anxiety disorders

Generalised anxiety disorders

Anxiety may coexist with depression or stand alone. Persistent states of anxiety and tension are particularly common after accidents of an especially frightening nature. In a survey of 188 consecutive victims of road traffic accidents, Mayou *et al.* (1993) found that one-fifth suffered from an acute stress syndrome as an aftermath, with mood disturbance and horrific memories of the accident. At follow-up 3 months and 1

year later, one-tenth of the series showed persisting mood disorder with anxiety as the major component. The acute stress syndrome was significantly related to neuroticism in the premorbid personality; continuing emotional distress was also especially likely in those who were psychologically and socially vulnerable, but was additionally strongly associated with chronic medical disability and social, financial and work problems. Harvey and Bryant (2000) found that those who develop symptoms of acute stress are at high risk of later PTSD. Concerns about cognitive performance contribute to anxiety and this often becomes evident as the patient returns to work. Problems with memory may be particularly difficult for the patient to evaluate. These concerns facilitate the development of behaviours such as indecisiveness, checking, avoidance of activities and a reluctance to take on new tasks. Similarly, anxiety is linked to somatic symptoms, for example headache when concentrating. Fear of walking unaided, because of feelings of dizziness or unsteadiness when walking, may be seen ('phobic imbalance'). This may reflect vestibular damage.

A man of 30 was seen 18 months after a head injury occasioned by a falling ladder. He had been only briefly concussed, but immediately afterwards became dizzy and vomited several times. Thereafter he experienced vertigo and nausea on sudden head movement, persisting on occasion 1 month later. During this time he became acutely phobic of enclosed spaces and travelling and gave in his notice at work. The dizziness subsided but the phobias persisted and intensified. He began drinking heavily. Detailed examination showed no evidence of brain damage, and it was strongly argued by the defendants that his present condition owed much to alcohol and little, if anything, to the injury. The genuineness of the phobias themselves was called into question.

However, examination revealed two striking signs. On tilting him backwards to a horizontal position with the head to one side he developed bursts of nystagmus, indicative of labyrinthine damage. Furthermore, on persuading him to enter the hospital lift he developed obvious signs of autonomic distress, with the pulse rate rising from 84 to 120 per minute. Subsequent neuro-otological examination showed that the right labyrinth was completely non-functioning. Crucial evidence was thus available to demonstrate labyrinthine damage accruing from the injury, and to confirm the genuine nature of his phobias (Lishman 1978).

However, in some patients anxiety aggravates the sense of unsteadiness.

Warden and Labbate (2005) describe a man who suffered a mild brain injury and fractured femur whose recovery of walking was slow. He developed a fear of falling and constant dizziness and blurred vision while walking, and later panic attacks with vertigo. He felt unable to walk without a stick even though his physiotherapists thought he should be able to walk unaided. He started abusing alcohol. His girlfriend noted that he was becoming increasingly dependent on her to help him walk, and that he walked *better* after drinking a few beers. With treatment, including sertraline, his symptoms subsided.

Estimates of the prevalence of anxiety disorders after head injury vary (Warden & Labbate 2005) and high rates have been reported after childhood head injury (Vasa *et al.* 2002). A reasonable estimate of the rate of generalised anxiety disorder at 1 year is 10–15% (Salazar *et al.* 2000). On the other hand, Deb *et al.* (1999b), also at 1 year post injury, found only 2% with generalised anxiety disorder but 9% with panic disorder; it is possible that small differences in classification of a patient into one diagnosis or the other may explain the difference with Salazar *et al.* (2000). In other words, about 10% probably suffer generalised anxiety with or without panic. Koponen *et al.* (2002) found 8% suffering panic disorder many years post injury. However, rates of anxiety, as defined by adjustment reactions, after TBI may not be much different from estimates of the pre-injury status (Fann *et al.* 2004).

Phobic disorders

Travel phobia is one of the commonest of phobic disorders after head injury and, not surprisingly, is seen particularly in those injured in an accident involving some means of transportation. Nervousness and travel avoidance are seen. The symptoms are often seen alongside more generalised symptoms of anxiety and it is not unusual to find heightened concerns for the safety of themselves and their loved ones in a variety of situations apart from travel. Understandably, the symptoms tend to be greatest in the form of transport where the injury was suffered, often the car. Typical symptoms of car travel phobia are a fear of speed, a need to maintain distance from the car in front, jumpiness and hyperarousal. The startle response may be exaggerated. As such there is often an overlap with PTSD. Symptoms are often worse when patients are being driven than when they are driving. Mayou *et al.* (2000) found that of those with mild head injury after a road traffic accident, 20% suffered travel anxiety 1 year later, not significantly different from the 16% observed in those who were injured in a road traffic accident but without a head injury. The authors note that there was probably less travel anxiety in those who had suffered major head injury.

Agoraphobia is not an unusual consequence of head injury. It is the commonest phobic disorder in the general population and therefore in a good proportion of cases might have been seen regardless of the head injury. However, in some cases anxiety related to, for example, difficulties coping with hustle and bustle, or concerns around falling if accidentally pushed in a crowd, or fears about losing one's way, seem to be instrumental in the development of agoraphobia. On the other hand, social avoidance, a common symptom after head injury, is rarely associated with a specific social phobia. Koponen *et al.* (2002) report that 5 of 60 patients assessed 30 years post injury had a specific phobia but give no further detail about the type of phobia.

Post-traumatic stress disorder

It is not unusual after a head injury for the patient to dwell on the circumstances of the injury or relive it in terrifying dreams. There may be marked startle responses and phobic avoidance of situations that bring the accident to mind. These are the typical symptoms of PTSD. It is now clear that symptoms of PTSD must be sought with care, in that patients may not always vouchsafe them directly. The disturbance can be long-lasting and disabling, and in chronic form the patient may merely present with non-specific complaints of irritability, insomnia, depression and general inability to cope.

Although many patients may report some of the symptoms of PTSD, far fewer meet full diagnostic criteria for PTSD. This requires that the patient is exposed to a terrifying experience and that symptoms from three domains should be present. The first consists of reliving the trauma, with nightmares, intrusive daytime recollections and sudden 'flashbacks' in which the traumatic event is re-experienced with realistic intensity. The second comprises avoidance behaviours in relation to reminders of the trauma. Closely related to avoidance there may be emotional numbing and detachment. The third includes heightened arousal and startle responses. Other non-specific symptoms include irritability and difficulties with memory and concentration. Using self-report measures to diagnose PTSD is not recommended and this is particularly the case after head injury because some of the symptoms of PTSD may be seen in head-injured patients regardless of any heightened emotional reaction to the injury. Sumpter and McMillan (2005) showed that whereas more than 40% of their 34 head-injured cases were classified as PTSD using self-report, e.g. with the Impact of Events Scale, only one was diagnosed as a case of PTSD using clinical interview.

In Mayou *et al.*'s (1993) survey of road traffic accidents, many of whom had not suffered a head injury, one-tenth of the victims were judged to meet criteria for PTSD during the subsequent year. The development of PTSD was not associated with a history of previous psychological problems; the principal and very strong predictor was the rating of 'horrific' memories of the accident at interview shortly after it

occurred. PTSD did not occur in subjects who had been unconscious and were amnesic for the accident. Similarly, Warden *et al.* (1997) were unable to find patients who met the full criteria for PTSD among 47 head-injured veterans who had sustained substantial PTA.

Others have demonstrated that PTSD symptoms may be found in those with severe head injury. Williams *et al.* (2002) used the Impact of Events Scale and found that 18% of 66 patients with a severe head injury and significant period of PTA had symptoms of PTSD. PTSD was diagnosed in over one-quarter of patients attending a brain injury rehabilitation unit after a severe head injury (Bryant *et al.* 2001) and was associated with worse outcome, suggesting that it was important not to overlook the diagnosis. However, others have found much lower rates for PTSD diagnosis. For example, of the 120 patients studied by Deb *et al.* (1999b) 1 year post injury, seven suffered nightmares and four were described as suffering symptoms of PTSD but in no case was a diagnosis of PTSD made. Only 3% of over 300 cases of mild head injury in McMillan's (1996) series were diagnosed with PTSD.

In a study of 307 patients admitted to a trauma centre, the rate of PTSD at 1 year of just over 10% was no different in those with mild TBI compared with those without a head injury (Creamer *et al.* 2005). Furthermore, within the group with mild TBI the prevalence of PTSD was about the same regardless of whether there was amnesia for the event. On the other hand, several studies have shown that greater amnesia for the event or injury severity is protective. Gil *et al.* (2005) diagnosed PTSD in 14% of 120 patients with mild TBI 6 months post injury and found that memory for the event made PTSD more likely. In a series of patients assessed on average about 8 weeks after injury, Feinstein *et al.* (2002) found that those with PTA greater than 1 hour were less likely to have symptoms of PTSD than those with PTA of less than 1 hour. Glaesser *et al.* (2004), studying 46 patients attending a neurological rehabilitation clinic after a head injury, found much higher rates of PTSD in those who were not unconscious for an extended period (27%) compared with those who were unconscious for more than 12 hours (3%; 1 of 31 patients). Intrusive memories were more frequent in patients who had not been unconscious.

It seems clear that aspects of the typical picture of PTSD can sometimes develop when the patient has lost consciousness after head injury, and in the presence of PTA. However, the symptom content of PTSD is probably a little different in those with head injury, compared with those without (Harvey *et al.* 2003). Though nightmares are quite common after head injury (Deb *et al.* 1999a), the content is not always directly related to images of the accident itself. There is less evidence of symptoms of re-experiencing; for example, six (13%) of Warden *et al.*'s (1997) patients met the avoidance and arousal criteria for PTSD while lacking the re-experiencing criteria. The following case is instructive (McMillan 1991).

A girl of 18 sustained a severe head injury in a road traffic accident and was unconscious for 3 or 4 days. She initially had a mild right hemiparesis, dysphasia, euphoria and poor memory, and spent 3 months in a rehabilitation unit. The duration of PTA was about 6 weeks. After 7 months she returned to her job as a bank clerk.

Fourteen months after the accident she was referred with symptoms of fatigue, poor concentration, dizziness, headache and difficulty in coping at work. There was a good deal of evidence of depression. However, other symptoms were not consistent with low mood or a post-concussion syndrome. She had intrusive thoughts several times a day about her friend who had died in the accident, and could not prevent these from entering her mind. They were triggered by situations where the two might conceivably have met, such as in the local supermarket. In addition she showed cognitive and physical avoidance of reminders of the accident, including hospitals in general. The thought of entering the rehabilitation unit where she had been treated was particularly anxiety-provoking. She did not talk about the accident to anyone, and continually postponed visiting the grave of her friend. She suffered from continual and irrational guilt, believing that she had somehow caused or failed to prevent the accident. Treatment involved cognitive-behavioural exposure techniques and resulted in marked improvement.

Co-morbidity. Post-traumatic stress disorder is associated with worse psychosocial outcome (Bryant *et al.* 2001). This probably partly reflects the fact that PTSD is often associated with anxiety and depression (Warden *et al.* 1997; Bryant *et al.* 2001; Levin *et al.* 2001). There is a marked overlap of PTSD with symptoms that are diagnosed as post-concussion syndrome (Bryant & Harvey 1999) and it is noteworthy that both conditions are predicted by early emotional reactions post injury, and may be prevented by early post-injury psychological treatments.

Mechanisms. King (1997) suggested that brief islands of memory, some of which were perhaps reconstructions, was one possible explanation for the emergence of PTSD after head injury. In other patients because the peritraumatic amnesia is negligible, there is no reason why a typical PTSD picture should not emerge. In those with significant amnesia implicit memory mechanisms may be at work. The following case illustrates the possible role of implicit memory.

A 30-year-old man was injured while unloading pallets of wood off a lorry. A laden pallet fell from the hoist and hit his head. He was unconscious for several hours and had an RA of about 2 days and a PTA of about 3 weeks. On recovery

from his PTA he suffered unpleasant derealisation experiences. For a period he became convinced that the whole event had been some sort of strange masquerade, played out by the hospital and others for an unknown purpose, but that in fact the accident had never happened. He recovered from this delusion but for many months symptoms of fatigue and poor concentration prevented him returning to work. During this period he and his wife spontaneously noted that when in the car, being driven by his wife, if they passed a lorry laden with pallets and carrying a hoist, he would become tense and suffer symptoms of anxiety. Yet he said that he did not remember that the accident had been caused by a falling pallet.

Conversion disorders

Hysterical symptoms have figured prominently in some series of head-injured patients, perhaps especially those admitted to army neurosis centres during times of war (Anderson 1942). The usual range of dissociative states may occur: fits, fugues, amnesias, Ganser states, motor paralyses, anaesthesias, and disturbances of speech, sight or hearing. The onset is usually soon after the injury, although later developments may occur in association with depression or when complex neurotic states emerge in relation to compensation issues. For example, Dalfen and Anthony (2000) identified four patients with a Ganser syndrome characterised by approximate answers (*vorbeigehen*) in a series of 513 cases of mild TBI followed up over the first year post injury; in three of the cases the syndrome was associated with an acute stress reaction. Only one was pursuing compensation.

Whitlock (1967) compared 56 patients admitted to psychiatric units with hysterical conversion symptoms, with a group of controls matched for age and sex but suffering from depressive or anxiety states. Almost two-thirds of the patients with hysterical disorders had suffered significant preceding or coexisting brain disorder, compared with only 5% of the controls. Head injury had preceded the onset of hysterical phenomena within 6 months in 21% of the hysterical patients but in none of the controls. It would seem therefore that head injury may be a more frequent antecedent of the clinical picture of hysteria than is commonly supposed. A significant proportion of the cases described by Eames (1992) as suffering hysteria after brain injury had suffered a head injury.

Obsessive-compulsive disorder

Obsessive-compulsive symptoms may emerge in susceptible individuals, usually as a colouring to pictures of depression or anxiety. However, OCD is not a common sequelae, Deb *et al.* (1999b) for example finding only 2 of 120 patients at 1 year to have OCD, probably not much greater than population norms. This is probably a more realistic estimate than

the 9% rate reported by Hibbard *et al.* (1998). Hillbom (1960) reported 14 examples among 415 cases (3.4%), of whom almost two-thirds had epilepsy, three times the prevalence among the patients generally.

McKeon *et al.* (1984) have reported four patients with severe OCD following directly from head injuries of moderate severity. Three were from a consecutive series of 25 patients suffering from obsessive-compulsive neurosis, the fourth from a pair of monozygotic twins discordant for the disorder. The prompt onset of symptoms, usually within 24 hours of injury, and the absence of premorbid obsessional traits in all but one case suggested that the brain trauma may have contributed directly to the neurosis by some physiogenic mechanism rather than acting as a non-specific stress. More recently, Berthier *et al.* (2001) described 10 cases of OCD secondary to head injury; six were mild, two moderate and two severe head injuries. Two patients were premorbidly indecisive and perfectionist and two had a history of PTSD related to sexual abuse. In all but one case the symptoms of OCD developed within 1 month of injury and, particularly in those with mild TBI, were associated with generalised anxiety or symptoms of PTSD. The symptoms of OCD were fairly typical although all 10 patients showed quite marked aggressive behaviour. Most showed both obsessions and compulsions. Common obsessions included fears of contamination and thoughts about symmetry and exactness. The most frequent compulsions were checking, cleaning and washing, and repeating rituals. Six of the patients showed obsessional slowness. Significant impairment of executive function was common.

Unlike the most common neuroses, Hillbom (1960) found that compulsive disorders tended to occur after reasonably severe rather than mild injuries. Of all the anxiety disorders, OCD is perhaps the most closely linked to changes in brain function, particularly involving the frontal lobes and their connections (Lucey *et al.* 1997). It is therefore not surprising that some case reports suggest a particular role of frontal injury (Bilgic *et al.* 2004; Ogai *et al.* 2005). On the other hand, psychosurgery for severe OCD also involves interrupting frontal connections. In the following case a patient previously seen in a general psychiatric clinic because of symptoms of OCD presented several years later to a specialist brain injury clinic following a head injury.

This lawyer presented in his early thirties with symptoms of OCD. Over several months he had developed gradually deteriorating symptoms of excessive checking and safety fears. He also had obsessional thoughts of harming those who were close to him. These symptoms had a very adverse effect on his marriage and for a period of time he was off work. He was successfully treated with cognitive-behaviour therapy but retained many obsessional and perfection-

istic personality traits. Several years later he fell and suffered a severe head injury with moderate bilateral frontal contusions. He attended the brain injury outpatient clinic for advice about his memory impairment. Neuropsychological testing showed significant but mild memory impairment and some evidence of executive impairment. Nevertheless, he was able to return to his job. In passing he noted that his tendency to worry excessively and his perfectionism no longer troubled him. If anything, his wife complained that he was a little too laid back.

Suicide

Death by suicide is considerably increased after head injury, occurring in about 1% of patients over the first 15 years or so after injury (Achté *et al.* 1971; Tate *et al.* 1997; Teasdale & Engberg 2001). Thus completed suicides have accounted for up to 14% of all deaths in the medium-term mortality studies, i.e. 20–25 years (Vaukhonen 1959; Achté & Anttinen 1963; Pentland *et al.* 2005). Increased levels of suicide relative to the general population have been reported among both brain-injured war veterans and civilian populations. Achté *et al.* (1971) identified 85 suicides in a cohort of 6498 Finish brain-injured veterans from the Second World War followed up over a 25-year period and estimated the suicide rate to be twice that of the general population. More recently, Teasdale and Engberg (2001) conducted a population study of suicide among patients admitted to any hospital in Denmark over a 15-year period with a diagnosis of head injury. The standard mortality ratio for suicide among people with cerebral contusions/traumatic intracranial haemorrhages (characterised as a severely injured group) was found to be four times greater than for the general population. The risk of suicide among people sustaining concussion or cranial fractures was also elevated, approximately double that of the general population. For all three groups, the risk of suicide was constant over the 15-year period, with no particular time period after injury being of significantly greater risk.

Epidemiological studies also suggest higher lifetime prevalence rates for suicide attempts, with Silver *et al.* (2001) reporting a rate of 8.1% among people with head injury in comparison to the general population (1.9%). This elevated risk was still significant after controlling for demographics, socioeconomic status, quality of life, alcohol abuse and the presence of any co-morbid psychiatric disorder. In an examination of the clinical features of suicide attempts, Simpson and Tate (2005) found that overdoses accounted for 62% of 80 suicide attempts committed by 45 people with head injuries, followed by cutting (17%) and miscellaneous other means. Precipitating factors included depression/hopelessness, relationship breakdown or conflict, social isolation and other stressors, e.g. lack of finances or work difficulties. Almost half (48%) went on to make one or more further attempts,

typically within 1 year of the index attempt. Two reviews of people who completed suicide after head injury identified post-injury rates of suicide attempt of 25% and 62.5% respectively (Achté *et al.* 1971; Tate, Simpson *et al.* 1997).

The relative contribution of premorbid, injury and post-injury factors to suicide and suicide attempts is still unclear. One major difficulty is that suicide and head injuries share a number of antecedent risk factors, including the predominance of young adult males, a history of substance abuse or psychiatric illness, and aggressive personality traits. In the case of mild head injuries, Teasdale and Engberg (2001) have suggested that these type of factors, present premorbidly or concomitant to the head injury, may be of more significance than the brain damage *per se* in the subsequent suicides. Further to this issue, Oquendo *et al.* (2004) found initial evidence that mild TBI may have a common antecedent risk factor to suicidal acts (i.e. suicide attempts) in non-brain-damaged populations, namely traits of hostility and aggression. In the study, the authors reported that these traits were the stronger predictors of suicide attempts, and that the mild TBI may have either been incidental or, at most, acted to exacerbate existing aggressive behaviour patterns.

In contrast, after severe injuries it is likely that the pattern of neuropathology, residual adaptive abilities, psychological reactions to the injury and the presence of psychiatric disorders play a significant role, both in completed suicide (Teasdale & Engberg 2001) and suicide attempts (Simpson & Tate 2005). In the case of suicides, lesions were commonly found in the frontal and temporal lobes of the brain (Vaukhonen 1959). The presence of a depressive psychosis or substance abuse has been identified as a significant risk factor in 5–40% of cases (Achté *et al.* 1971; Tate *et al.* 1997). Clinically, studies have also reported the presence of adaptive problems, including financial difficulties, vocational problems, relationship disputes and stress in marital relations, and personality change (Vaukhonen 1959; Hillbom 1960; Achté *et al.* 1971; Tate *et al.* 1997). Risk factors for suicide attempts include a post-injury history of psychiatric/emotional disturbance or substance abuse, as well as clinically significant levels of suicide ideation (Simpson & Tate 2002, 2005). There was a powerful interaction between risk factors such that patients with both a post-injury history of psychiatric disturbance and substance abuse were 21 times more likely to have made a post-injury suicide attempt than patients with neither (Simpson & Tate 2005). Premorbid risk factors cannot be discounted, even in those with more severe injuries. With regard to treatment, practice options suggested by current research include reducing the lethality of the environment, following published guidelines in the prescription and administration of medication, treatment of comorbid substance abuse or depressive disorders, and increased monitoring/support for at least 1 year following a suicide attempt.

Mild TBI

Observations on the sequelae of mild TBI are intimately linked to the discussion of the post-concussion syndrome (see below), one possible outcome of mild TBI. However, because post-concussion syndrome may also follow moderate and severe injuries, it is discussed separately. This first section concentrates on what is known about the outcome of mild TBI in terms of neuropathological and imaging findings, symptoms, cognitive impairment and recovery of disability and handicap. Some of these matters have already been considered, but with reference to the full range of head injury severity. Over the last decade many studies have focused on mild TBI in an attempt to define its natural history. Studies of concussion in sport have provided unique opportunities for observation.

Definition of mild TBI

It has been noted that there is much greater consensus on the definition of mild TBI than for moderate and severe TBI (Classifying head injury severity, earlier in chapter). There is general agreement that the core criterion, in terms of defining the boundary between mild and moderate head injury, is that the GCS score should not be less than 13. In terms of the boundary between no significant head injury and mild head injury, most will allow any disturbance of consciousness, not necessarily loss of consciousness, such that the patient meets the criterion of having suffered a concussion (see Impairment of consciousness, under Acute effects of head injury, earlier in chapter). This therefore distinguishes mild TBI from what might be called a trivial head injury, in which there was a blow to the head, but with no subjective effects on the mental state or neurological function. Whether a person can suffer a TBI in the absence of a blow to the head, simply on the basis of acceleration/deceleration forces transmitted to the head by the neck (e.g. whiplash injury), is uncertain. More recently there has been interest in the potential effects of blast injury, and there is uncertainty as to the extent of any brain damage caused by the air pressure wave of an explosion. Some definitions of mild TBI will exclude those with a skull fracture or focal neurological signs whose injury is regarded as at least moderate. Even more restrictive are those definitions that do not allow focal intracranial abnormalities on brain imaging. However, for the purposes of the discussion here, these more restrictive definitions are not used. Most definitions exclude those with penetrating injury.

Two observations from study of the outcome of mild TBI have a bearing on the definition. On the one hand there appears to be no stepwise effect of loss of consciousness on outcome (see below). On the other, comparing those with GCS scores of 15 with those whose GCS score is 14 or 13, there is a gradient of effect. For example, Kraus *et al.* (1984) found that those with a GCS score of 15 stayed on average 2 days in hospital, whereas those with a GCS score of 13 or 14 stayed

on average 3 days. Hsiang *et al.* (1997) reported good outcome at 6 months in 98%, 93% and 76% of those with GCS scores of 15, 14 and 13, respectively. The outcome for patients with a GCS score of 15 and with acute radiographic abnormalities was about the same as all those with GCS scores of 13 and 14, and worse than those with a score of 15 but without any findings on CT. When considering these findings it must be acknowledged that one explanation is that lower GCS scores are probably associated with more severe injury generally. McCullagh *et al.* (2001) did not find an effect of GCS score within the range 13–15 on outcome about 6 months post injury, but the study was based on clinic referrals and therefore exposed to ascertainment effects.

Thus the definition of mild TBI in fact covers quite a range of injury. For example, the definition will include the injury suffered by a footballer who suffers a 'ding' when hit on the side of the head and is momentarily dazed. It will also cover somebody who is unconscious for 20 minutes after a fall from 10 metres and is still a little confused 12 hours later in casualty. Yet the outcome from these two patients is likely to be rather different.

Evidence for permanent damage to the brain in mild TBI

Two questions arise in relation to pathological sequelae of mild head injury. What are the risks of developing significant focal brain injury, e.g. intracranial haematoma, that is evident clinically or on neuroimaging? The second question is much more difficult to answer and therefore contentious: how many suffer diffuse axonal injury, perhaps invisible on neuroimaging, which nevertheless explains some of the post-concussional symptoms?

The first question is of most interest to the neurosurgeon or emergency physician in relation to triage and follow-up of patients presenting after a mild head injury. A meta-analysis (af Geijerstam & Britton 2003) concluded that:

Of 1000 patients arriving at hospital with mild head injury, 1 will die, 9 will require surgery or other intervention, and about 80 will show pathological findings on CT. At least these 8% of patients will probably need in-hospital care.

This is in keeping with the more recent series of Fabbri *et al.* (2004); of over 5000 patients, 6% had an intracranial lesion on CT brain scan and 1% required neurosurgery. Patients at higher risk of complications are those with neurological signs, older age, alcohol abuse or a GCS score of 13 or 14 (Culotta *et al.* 1996; Gomez *et al.* 1996; Servadei *et al.* 2001). For example, CT abnormalities are found in 5% of those with a GCS score of 15 but in 30% of those with a GCS score of 13 (Borg *et al.* 2004). For those with a GCS score of 15 when this is associated with severe headache, nausea or vomiting there is a higher risk of an abnormality on CT brain imaging (Batchelor & McGuinness 2002). It is worth noting that although only a very small proportion suffer complications, because mild head injury is so much more common than

moderate and severe head injury, a significant proportion of those who do suffer complications requiring surgery have mild injuries. For example, more than 40% of all patients with depressed fractures have never lost consciousness (Jennett 1989). Definite post-traumatic MRI abnormalities were found in 5 of 80 patients with mild head injury, with some abnormality in a further 21. Abnormalities on MRI did not predict outcome, except for early attentional problems (Hughes, Jackson *et al.* 2004).

Thus some sequelae will be readily evident on brain imaging. In the majority of patients with mild head injury, even using the sensitive structural MRI techniques (see below), the brain appears normal. However, a normal MRI scan does not rule out the possibility of diffuse axonal injury. Three lines of evidence suggest that diffuse axonal injury may occur after mild head injury.

1 Anecdotal studies describe evidence of diffuse axonal injury at post-mortem in patients who have had a mild head injury and died shortly after from other causes (Oppenheimer 1968). Using more sensitive techniques, which are however probably less specific and therefore run the danger that they may be sensitive to effects other than trauma, Blumbergs *et al.* (1994) found evidence of axonal damage using staining to amyloid precursor protein in five elderly patients, average age 77 years, dying mostly from respiratory causes between 2 and 99 days after mild head injury.

2 Povlishock and Coburn (1989) argue that brain injury in the cat produced by fluid-percussion is an appropriate model of human mild head injury. When given a very brief anaesthetic to cover the procedure, cats recover in minutes with no residual signs evident at 1 day and usually no macroscopic findings in the brain. Yet there is widespread evidence of diffuse axonal injury, particularly involving long tracts.

3 Specialised neuroimaging techniques suggest that white matter injury may be seen in patients with mild head injury: diffusion tensor imaging and magnetisation transfer imaging on MRI may show abnormalities in normal-appearing corpus callosum after mild head injury (see under Neuroimaging and head injury, earlier in chapter).

However, even if neurones are not permanently damaged after mild head injury, is there good evidence for neuronal dysfunction? If so, for how long? Various methods have been used to look for evidence of significant brain dysfunction after a mild injury. One critical issue is whether the studies have been performed in unselected patients, which usually requires recruitment from a casualty department at a time close to the injury, or in selected cases, for example from patients attending an outpatient clinic to which they have been referred. Studies on selected cohorts are at risk of over-estimating any association between mild head injury and abnormal findings. Thus for example several studies using functional imaging in symptomatic patients have shown areas of hypometabolism after mild head injury (see Functional neuroimaging: studies of cerebral blood flow and

metabolism, earlier in chapter) but this may have more to do with the fact that they have symptoms than because they have suffered a head injury. On the other hand, the findings of McAllister *et al.* (1999), which show convincing changes in the organisation of cerebral function in the early weeks after a mild head injury, were on unselected cases of mild head injury.

Most would agree that the routine EEG is not helpful. There has been greater interest in evoked potentials, including brainstem auditory-evoked potentials and visual-evoked potentials and event-related potentials like the P300. However, perhaps because some of these are highly specialist techniques requiring careful interpretation, early findings have not always been replicated and have not become part of routine clinical practice. Gaetz and Bernstein (2001) (and see below) in their review of electrophysiological procedures for the assessment of mild TBI conclude that cognitive event-related potentials seem to be more sensitive to injury than evoked potentials. There is some evidence that these effects may be long-lasting (Bernstein 2002). Whether cognitive event-related potentials have any value in the work-up of patients with mild head injury or post-concussion syndrome will depend very much on whether they are able to distinguish the effects of the head injury from any comorbid condition such as depression.

Two studies of motor control have found mild impairments in patients after mild head injury despite an absence of neurological signs. Postural control abnormalities were found in a highly selected group of 15 patients who complained of imbalance after mild head injury (Geurts *et al.* 1999). These patients had larger centre of pressure fluctuations, i.e. swayed more, when standing on a balance platform than did controls. The changes correlated with a speed of information processing task not with measures of emotional well-being, suggesting that they reflected some underlying brain dysfunction. Heitger *et al.* (2004) found subtle impairments of oculomotor control and visuomotor arm movement control in 30 patients within 10 days of mild head injury. The findings were interpreted as evidence of impairment in visuomotor networks linking visual input to motor output. Impairments did not correlate with neuropsychological findings, suggesting that the effects were independent of any generalised psychomotor slowing seen early after mild head injury. However, these findings need to be interpreted alongside the observation that the pattern of motor impairment in some patients after mild head injury may not correspond with physiological pathways (Greiffenstein *et al.* 1996), suggesting that non-organic factors are responsible.

Cognitive impairment after mild head injury

Cognitive impairment is likely to be the direct result of the damage to the brain tissue. Minor injuries are compatible with full intellectual recovery, in the sense that the patient feels himself to be unimpaired and psychometric tests reveal no deficits in performance, even when indubitable loss of

consciousness has occurred. Levin *et al.* (1987c) followed a group of patients with minor head injury. Patients with a previous history of alcohol or drug abuse, previous head injury or a history of neurological or psychiatric disorder were excluded. Tests of memory, attention and information processing showed impairments at 1 week, but these generally resolved during the next 3 months. Somatic complaints and affective symptoms also diminished but cleared less completely. It was concluded that a single uncomplicated minor head injury produces no permanent neurobehavioural sequelae in the great majority of patients, provided they have been free from pre-existing neuropsychiatric disorder. It is possible nevertheless that subtle changes, too minor to be detected, may still exist.

Over recent years there have been several systematic reviews that have used metaanalysis to describe the neuropsychological outcome of mild TBI. The meta-analyses are based on the effect size comparing injured with control subjects. The effect size is the size of the difference between two groups as a proportion of the standard deviation of the scores. Thus an effect size of 0.5 indicates that one group did worse or better by half a standard deviation. As an approximation, effect sizes of 0.2 are usually considered to be small, 0.5 is moderate and 0.8 is large. The advantage of using the effect size is that it can be used as a common metric to compare studies that have used very different neuropsychological tests.

Quality is ensured by criteria that exclude studies on cohorts recruited from clinics or medicolegal practice because the ascertainment of such patients is strongly determined by the presence of symptoms. On the other hand, for example, a study recruiting all patients with mild head injuries presenting to an emergency department would be allowed. Some of the reviews (Binder *et al.* 1997; Frencham *et al.* 2005) have demanded at least 50% of the sample are followed up, to minimise the risk that the measured sample is not representative of all injuries. Using these criteria Binder *et al.* (1997) only examined papers with follow-up intervals of longer than 3 months post injury and found little evidence of neuropsychological impairment. There was some evidence that measures of attention were slightly impaired. Frencham *et al.* (2005) used the Binder *et al.* criteria to identify studies published since 1996 and therefore not included in the earlier review. They also included studies with shorter post-injury intervals to determine what impairments might be seen early after injury. The overall effect size for the 12 studies of less than 3 months was 0.33, which was statistically significant. On the other hand, the effect size for the 17 studies greater than 3 months was non-significant at 0.11. Thus early post-injury impairments are largely resolved by 3 months. The authors also examined whether any particular psychological domain was particularly vulnerable. The largest effects sizes were for speed of information processing (0.47), memory and executive function (both 0.3), and tests of attention (0.25); all were statistically significant. However,

measures of intelligence, both verbal and performance IQ, were not significantly impaired. They noted that even for the test with the biggest difference between controls and injured (speed of information processing), the effect size of 0.45 meant that only one-third of head-injured patients would be worse than any of the control subjects; in other words, two-thirds of the cohorts would overlap in their scores. Schretlen and Shapiro (2003) identified 16 studies many of which were different from the Frencham review, and obtained very similar results. Effects sizes at less than 7 days, 7–29 days, 30–89 days and greater than 90 days were about 0.5, 0.3, 0.1 and 0 respectively.

Belanger *et al.* (2005) took a slightly different approach in their meta-analysis. They wanted to examine the effects on outcome of litigation or being seen in a clinic, so they included all studies and then collated them according to the source of ascertainment. A dramatic effect of ascertainment was seen for the studies of patients after 3 months. For the eight studies with unselected samples assessed after 3 months the effect size was 0.04; in other words, in agreement with the findings described above, there was no evidence for neuropsychological impairment after 3 months. This compared with an overall effect size of 0.63 for the 23 unselected sample studies assessed within 3 months after injury, and in whom the most vulnerable domains were delayed memory and fluency (1.03 and 0.89 respectively). However, for both selected groups, litigation and clinic based, effect sizes after 3 months were 0.78 and 0.74 respectively, and there was a fairly consistent effect across all psychological domains. Across eight litigation studies there was a hint that impairments deteriorated over time; the overall effect size for the two studies before 3 months was 0.52, and for the six studies after 3 months was 0.78. It is worth noting that these patients who had mild head injuries but who were involved in litigation did almost as badly as unselected patients with moderate/severe head injury in whom an effect size of about 0.8 was found in the meta-analysis of Schretlen and Shapiro (2003). Despite this, it is important not to conclude from these findings that litigation causes this level of symptoms. At least part of the explanation will be a large ascertainment effect, such that the litigant cohorts will have selected, i.e. not included, those who do well. In other words, it is only those with a lot of problems who are recruited into the litigation cohort; for those who do not have any problems, there is no point seeking compensation.

These reviews suggest that there may be some slight enduring impairment in some after mild head injury. Vanderploeg *et al.* (2005) have used follow-up of over 4000 Vietnam veterans about 15 years after they had been discharged from the military in order to examine the effects of mild head injury; 254 veterans said that they had suffered a head injury with loss of consciousness since discharge which had not required hospitalisation. These veterans with a history of

mild head injury, on average about 8 years before testing, were slightly impaired on PASAT and on a measure of proactive interference of memory, although on many tests no impairment was seen.

Head injuries in sport provide a unique opportunity to consider the effects of very mild injury. They are relatively homogeneous, with only exceptional cases having more than a few minutes of loss of consciousness. They are relatively predictable. For example, an American footballer has about a 5–15% chance of sustaining a concussion during the course of a season. Those who are not concussed can act as a ready source of controls. And they are relatively easy to capture. Many of them occur during competitive play with trainers, medics and sometimes television crews to observe what happened.

In an interesting study Barth *et al.* (1989) investigated very mild head injuries (loss of consciousness less than 2 minutes) among university football players, comparing PASAT scores at 24 hours and thereafter with pre-injury performance. Players with mild orthopaedic injuries served as controls. When tested at 24 hours after head injury, PASAT scores failed to improve as they did in controls due to practice effect. Thereafter, serial testing showed resolution of the impairment. Symbol-digit decoding revealed a similar pattern of transient deficits. Symptom scores for headache, dizziness, nausea, weakness and difficulty with memory were also increased at 24 hours, and then subsided to normal by 10 days. Thus a single very mild head injury caused cognitive/information-processing deficits that could be documented at 24 hours, and which were accompanied and followed by subjective complaints.

These findings have been backed up by a recent meta-analysis of 21 studies (Belanger & Vanderploeg 2005), which confirmed that by 7 days post injury it was difficult to identify much cognitive impairment compared with controls. In the first 24 hours after injury the average effect size was 0.97, with the greatest impact on memory and tailor-made test batteries (effect sizes of about 1.5). For studies between 1 and 7 days the effect size was down to 0.43, and for most assessments longer than 1 week after the injury there was little if any impairment. The effects of sports injuries will be discussed in more detail below, including a discussion of the possible confounding effects of practice, prior cognitive impairment and multiple concussions. However, it is safe to conclude that only the occasional head injury sustained in sport will produce cognitive impairment beyond 2 weeks after the injury, yet in the first 24 hours after injury many will have significant difficulties with memory and slowing of information processing.

This survey therefore indicates that the majority of the athletes are asymptomatic within a day or two, whereas many of those seen in casualty will require several weeks to recover. Much of this difference is simply because the sports

injuries are milder. Although there are exceptions (Raisanen *et al.* 1999), most athletes with concussion never get to hospital, would have a GCS score of 15 were it measured 20–30 minutes post injury (i.e. at about the same time after injury as the GCS is measured in casualty), and lose consciousness if at all only very briefly. However, it is also possible that other factors also determine the athletes' better outcome. Physical factors may be relevant. The athlete's head and brain may be more resilient and the physical blows suffered in sport generally less harmful. Psychological factors probably also play a part; most athletes are highly motivated to return to playing and are unlikely to regard anybody to blame for the injury.

In summary, studies of neuropsychological functioning after mild head injury point to some disturbances in cognitive functioning shortly (i.e. in the first few days or weeks) after injury, with these impairments typically most apparent on tasks with an attentional and/or processing speed component (Cicerone & Azulay 2002). However, evidence for persisting impairments following mild head injury from prospective longitudinal studies is somewhat weaker.

Loss of consciousness and outcome

It is sometimes said that, within the spectrum of mild head injury, whether or not somebody loses consciousness is immaterial to the outcome. In other words, those who are concussed but do not lose consciousness do as badly as those who lose consciousness. For example, Sharma *et al.* (2001) found that a history of unconsciousness did not correlate very well with the risk of intracranial complications. This story starts with the finding of Lidvall *et al.* (1974) that concussional intensity is not a good predictor of the cognitive impairment found in the days after injury. In a similar study based on patients attending casualty with a mild head injury, but not including those with a GCS score of 13, Lovell *et al.* (1999) compared the 60% who had loss of consciousness with the 20% who definitely did not. They were tested on average 1–2 days post injury on a range of neuropsychological tests and no differences were found between those with and those without loss of consciousness. Further support came from studies of concussion in sport. McCrory *et al.* (2000) studied 23 players concussed during a game of Australian rules football, of whom three had lost consciousness. Loss of consciousness did not predict slower information processing, measured using the digit–symbol substitution test, within 15 minutes of injury (the data are not given). Erlanger *et al.* (2003) assessed 47 concussed college American footballers, of whom 12 had suffered loss of consciousness. At the sideline of the playing field in the minutes after injury, those who had lost consciousness had more symptoms. However, when assessed 2 days later, loss of consciousness did not predict who had more symptoms. Somewhat more ambivalent is the study of 78 concussed

high school and college amateur athletes (69% American football) (Collins *et al.* 2003); 15 suffered loss of consciousness, which in 11 lasted less than 1 minute. When assessed on average 1–2 days post injury, 34 cases had poor outcome, in terms of symptoms and memory difficulties; 21% of the poor outcome group compared with 12% of the good outcome group had suffered loss of consciousness (not statistically significant). One study has suggested that the timing of the measures may be critical in determining whether loss of consciousness has an effect on outcome (McCrea *et al.* 2002). Of 91 college athletes who suffered a concussion, when tested 15 minutes later using a brief battery of tests of orientation, memory and concentration, by far the greatest impairment was seen in the seven patients who had suffered loss of consciousness. However, by 48 hours there was no difference.

Therefore when loss of consciousness lasts only a few seconds or at most a minute or so, effects are seen when testing is done within about 15 minutes of the injury; brief loss of consciousness does produce greater impairment than concussion without loss of consciousness. However, this effect of brief loss of consciousness is quickly lost and within about 24 hours can no longer be reliably detected.

Multiple concussions and outcome

Discussion of the effects of multiple concussions is most relevant to the sequelae from mild head injury; it is rare for an individual to suffer multiple moderate to severe head injuries, but multiple mild head injuries, particularly in sport, are not all that uncommon. Gronwall and Wrightson (1975) were able to find 20 cases and, using PASAT, they demonstrated that rates of information processing were slower after a second mild head injury than after a single injury of equivalent severity, despite a mean of 4.5 years between the two. The time taken to recover to normal levels of functioning was also significantly delayed. Teasdale and Engberg (2003) studied the cognitive test scores of young men aged about 18 drafted into the Danish army. National health records were used to identify those conscripts who had suffered a mild head injury, requiring at most 24 hours admission, when younger. Those with a history of concussion did worse than control uninjured men; their chances of scoring in the 'dysfunctional range' were raised, with an OR of about 1.4. More men (27%) of those who had suffered two or more concussions scored in the dysfunctional range than those who had only suffered one head injury (23%). This trend was not significant; however, if only those with injuries before age 11 years were analysed, men with double concussion did significantly worse (27% vs 21%). The study therefore provides gentle support for the hypothesis that two mild head injuries in childhood are worse than one. However, an equally plausible explanation for the findings is that those of lower IQ are more injury prone.

This reverse causality explanation also has to be considered in studies of sport injury. There is little doubt that certain athletes are injury prone. The proportion of athletes with multiple concussions exceeds that predicted by chance. The relative risk of sustaining a concussion over a two-season follow-up of American football players if that person had already suffered one or more head injuries was 16% compared with 3% for those with no history of concussion (Zemper 2003). However, some of this may be because one concussion leads to another. Guskiewicz *et al.* (2003) identified 12 within-season repeat concussions in athletes, and in 11 the second injury occurred within 10 days of the first. Several studies on athletes have examined the hypothesis that multiple concussions are associated with worse outcome, but none have prospectively followed athletes from before their first ever concussion to see if their worse performance in fact antedated any head injury. In general, those with a history of previous concussion do worse after the index concussion (Collins *et al.* 1999; Iverson *et al.* 2004; Moser *et al.* 2005). One study found more loss of consciousness (~10% vs ~4%) and slower rates of recovery in those with previous concussion (Guskiewicz *et al.* 2003). In a study of 698 jockeys, 108 said that they had suffered a head injury and of these 27 reported two or more (Wall *et al.* 2006). Those with repeat injury did worse than both single injury and those with no injury on the Stroop test of response inhibition. However, two studies of athletes have failed to find any differences between those with two previous concussions and those with one (Macciocchi *et al.* 2001; Iverson *et al.* 2006). The special case of boxing is discussed under Head injuries in sport, later in chapter.

Two studies have considered the possibility that subtle cognitive effects of a mild head injury may only become manifest when the reduced cognitive reserves have to be called upon. Ewing *et al.* (1980) showed impairment on tests of memory and vigilance under conditions of hypoxic stress 1–3 years later, although there was no suggestion that this was related to the presence or absence of post-concussional symptoms. On the other hand, Klein *et al.* (1996) argued that involuntional change would expose any reduced reserve and therefore tested 25 older people who had suffered a mild head injury many years before and compared their performance with 20 age-matched controls. They found no difference.

Typical post-concussion symptoms after mild head injury

Organic contributions to the picture in the days following injury are suggested by the frequency of headache, dizziness, fatigue, difficulties with concentration and memory, and noise sensitivity. Within 1 week of injury, headache, dizziness, fatigue and sensitivity to noise and light are commoner after minor head injury than after injury to the limbs (McMillan & Glucksman 1987). The three symptoms

showing the greatest discrimination between the head injured and the control group within 1 month of injury have been found to be fatigue, doing things slowly and poor balance (all much more common in the head injured group) (Paniak *et al.* 2002b). By 1 month, and certainly by 3 months, many of these somatic symptoms of concussion will have recovered and if the patient remains symptomatic, emotional symptoms are likely to have become more evident. Lidvall *et al.* (1974) found that patients tended not to report anxiety and irritability in the first 2 weeks, but that by 3 months anxiety was one of the most common symptoms. Headache improves rapidly over the first few days and weeks, but remains high on the list of most frequent symptoms in many studies, even as late as 1 year. However, headache is quite common in the general population, so it is difficult in many cases to confidently predict that late headache is due to the head injury (see below for more detailed discussion of headache and dizziness). Common symptoms at 3 months and 1 year include irritability, fatigue, anxiety and poor sleep (Lidvall *et al.* 1974). When compared with control populations, those who have suffered mild head injury still report more somatic post-concussional symptoms late after injury. Depression after mild head injury is more likely in those with early depressive symptoms and who are older (Levin *et al.* 2005). Because depression is associated with poor outcome (Rapoport *et al.* 2003), those who do badly after mild head injury are sometimes described as the ‘miserable minority’ (Ruff *et al.* 1996b).

Recovery of symptoms after mild head injury

Time course of recovery

It is less easy to come to any firm conclusions about the time course of the recovery of symptoms after mild head injury than it is for the recovery of cognitive impairment. The reported rates of symptoms vary widely from one study to another. Also it may be much more difficult to confidently attribute any symptoms that are found to the head injury (see below). However, the trajectory of the recovery of symptoms after concussion in sport is relatively easy to follow. Few sportsmen describe symptoms attributable to the concussion beyond a week or two (McCrory *et al.* 2000). This is consistent with Lowdon *et al.* (1989) who studied the most minor head injuries seen in casualty, those with a PTA of less than 15 minutes. Although 90% had symptoms in the aftermath, by 2 weeks the majority of patients were symptom free. The median time off work was 1 week.

However, if all mild head injuries, defined by a GCS score of 13–15, presenting to casualty are followed up, then symptoms lasting weeks and months will be found in a significant proportion. The picture is probably worse if those with complicated injuries, for example with abnormalities on CT brain scan or with skull fractures, and those with previous head injuries or psychiatric problems are included. Cohorts

that have been subject to ascertainment bias may suggest even greater morbidity. While this bias is readily apparent if the patients are recruited from clinics to which they have been referred because they are symptomatic, even those agreeing to take part in prospective studies recruited in casualty may be biased towards those with more severe injuries compared with those who do not consent (McCullagh & Feinstein 2003).

In Lidvall *et al.*'s (1974) prospective study there was a marked and continuing decline in the percentage of patients displaying one or more post-concussional symptom, from 73% at 2 days to 24% at 3 months, the fall being particularly marked during the first post-injury week. In the longer term such changes doubtless continue. Reviews of the literature (Iverson 2005; McAllister 2005) indicate the wide variation in the proportion of patients reporting symptoms at time points during the first year after a mild head injury. The figures from the review by Jacobson (1995) are worth quoting: persistent complaints are observed in 25–65% at 3 months, in 21–24% at 6 months, and in 14–18% at 1 year.

Perhaps of more interest is the proportion of cases with significant disability. Some indication of this is the presence of multiple symptoms. Of the 83 patients followed up by Lidvall *et al.* (1974), nine had numerous complaints at each time point over the first 3 months, with some tending to get worse over time. Ingebrigtsen *et al.* (1998) estimated that at 3 months 40% had three or more symptoms. Of those followed up by Deb *et al.* (1998), 17% at 1 year were diagnosed as psychiatric cases; they had to have loss of consciousness or abnormal findings on radiology or neurological examination to be included. On the other hand, only about 2–5% of those with uncomplicated mild head injury followed up by Alves *et al.* (1993) had multiple symptoms at 1 year, a figure which tallies with the 5% of Rutherford *et al.* (1979). Jones (1974) found that only 1% of patients were still symptomatic after 1 year, but this low rate is probably because the study was designed to detect neurosurgical complications rather than neuropsychiatric sequelae, and because very mild injuries were included.

Estimates of overall outcome have also been diverse. Hsiang *et al.* (1997) found good outcome in over 90%, but in the series by Deb *et al.* (1998) only 70% had good outcome as defined by the Glasgow Outcome Scale. Even worse are the figures from Glasgow, where 47% were disabled at 1 year (Thornhill *et al.* 2000). This figure, the same as those with severe injury, perhaps reflects the high levels of morbidity in the sample before the injury; alcohol was involved in about 60% of the injuries and only 35% were employed, a housewife or in further education before the injury. Van der Naalt *et al.* (1999b) identified 12% with moderate disability at 1 year in a follow-up of patients with GCS score 13 or 14, while the rest (88%) had good outcome; 79% had returned to work. This latter figure is consistent with that of Symonds and Russell (1943) who found that 88% went back

to work, all within 6 months, with 75% of the total sample being rated fully fit. However, the figures from Ruffolo *et al.* (1999) are less optimistic; only 21 of their 50 patients (42%) who suffered a mild head injury in a motor vehicle accident and who were in work at the time of the injury had returned to work when followed up on average 7 months after the accident.

Interpretation of these findings is complicated by the possibility of high rates of morbidity in those who suffer injuries other than head injury. High rates of post-concussional symptoms are found in those with chronic pain (Iverson & McCracken 1997) and even in the general population (Chan 2001), particularly those who are depressed (Iverson & Lange 2003). Indeed in a study comparing those with and without a head injury and with and without depression it was depression, rather than a head injury, that largely accounted for symptoms on the MMPI (Aloia *et al.* 1995). Some studies on mild head injury have addressed these concerns using a control population as a comparator. Within 1 month after injury Paniak *et al.* (2002b) were able to demonstrate greater morbidity in those with mild head injury than in controls without any injury. Kraus *et al.* (2005) compared over 235 patients with mild head injury (72% of those eligible) with 235 patients with injuries of comparable severity but not involving the head, recruited from casualty and followed up at 6 months. Fatigue was one of the commonest symptoms in both cohorts (about 43%). Headaches, dizziness, blurred or double vision and memory problems were more common in those with head injury. However, in terms of morbidity there was little to choose between the two groups. In fact more of the head-injured cohort had returned to work. Two studies have examined consecutive admissions to casualty following a motor vehicle accident 6–9 months after the accident to see whether those who had suffered a mild head injury in the accident did worse than those who had not. Friedland and Dawson (2001) found that on average scores on the Sickness Impact Profile, which measures perceived changes in daily activities and behaviour, were doubled in those with mild head injuries, although on several other measures, including rate of return to work and scores on the General Health Questionnaire, no differences were found. Bryant and Harvey (1999) found no differences in reporting rate across several symptoms including fatigue, dizziness and headache, but did find at least double the rate of irritability in those with head injury 6 months after the accident. Jurkovich *et al.* (1995) examined all those with lower limb fractures as the index population, and found that those who also had a head injury did almost twice as badly on a measure of psychosocial disability both at 6 months and 1 year. Those with severe head injury were excluded from the study. However, two studies comparing mild head injury with those who suffer injuries but not to the head, with follow-up at 1 year, have been more equivocal: Mickeviciene

et al. (2004) found some evidence for greater symptoms of memory and concentration problems and dizziness and fatigue; Hanks *et al.* (1999) used the Katz Adjustment Scales and found no evidence for greater emotional problems. Studying patients attending pain clinics as opposed to a brain injury follow-up clinic, Smith-Seemiller *et al.* (2003) found more evidence of noise and light sensitivity and concentration problems in the head-injured cohort, with a trend for them also to have more headaches.

In summary, patients weeks and months after a mild head injury probably do suffer more symptoms than those with other injuries and compared with the general population, but the effect is not large. There is considerable overlap of symptoms across these groups, although those with mild head injury tend to have more symptoms that are typically associated with head injury, including concentration problems, headache, dizziness and noise and light sensitivity. Those who are depressed tend to report more symptoms, whether or not they have a head injury.

Predictors of symptoms

An understanding of the risk factors for doing badly after mild head injury may allow early therapeutic interventions aimed at preventing the development of a persistent post-concussion syndrome in those at risk. Identification of risk factors is best achieved using prospective follow-up of patients attending casualty, and this is what is discussed here. Case-control studies which compare those who are recruited into the study because they are symptomatic with others who are not are more exposed to bias. Nevertheless, case-control studies do add to a better understanding of the post-concussion syndrome and are discussed below.

It is probably useful to distinguish predictors of symptoms within weeks of injury from predictors of symptoms present months and years after injury. Almost all studies that examine the effects of age find that being older is a risk factor for symptoms both early and late after injury. In some studies women do worse (Alves *et al.* 1993; Ponsford *et al.* 2000; McCauley *et al.* 2001) but this is not an entirely consistent finding (Savola & Hillbom 2003). It is probably the case that organic factors are best at predicting early post-injury symptoms. For example, post-concussional symptoms at 1 week may be more common in those with CT brain scan or SPECT abnormalities within the first 3 days (Gowda *et al.* 2006). Perhaps those with the dopamine D₂ receptor T allele are at greatest risk (McAllister *et al.* 2005); they had worse performance at about 5 weeks post injury on a measure of response latency. Poor performance on two or more of a battery of neuropsychological tests performed within 24 hours of injury was found to predict post-concussional symptoms up to 3 months after injury, but not at 6 months (Bazarian *et al.* 1999). Two studies, both with reasonable follow-up rates (De Kruijk *et al.* 2002a; Savola & Hillbom 2003), found elevated S-100B and

the presence of dizziness or headache in casualty to predict the presence of post-concussional symptoms around 1–6 months later. It is possible that a normal HMPAO-SPECT within 4 weeks of a mild head injury excludes poor outcome at 1 year (Jacobs *et al.* 1996). Rutherford *et al.* (1977) were able to show an association between the prevalence of symptoms at 6 weeks and the presence of diplopia, anosmia or other neurological abnormalities during the first 24 hours after injury. The effect was still present at 1-year follow-up (Rutherford *et al.* 1979).

However, emotional factors are probably the best predictors of poor outcome, particularly when symptoms become more persistent. Their effects can be discerned even within a few weeks. Rutherford *et al.* (1977) found that the symptom rate was significantly higher at 6 weeks in those who blamed their employers for their accidents compared with those who blamed themselves. Lidvall *et al.* (1974) found that patients with post-concussional symptoms during the early months had suffered more anxiety about the accident from the earliest stages, more worries about other ailments and more fears that they had sustained serious and possibly permanent brain damage. King *et al.* (1999) showed that those who reported more anxiety and depression and who had higher scores on the Impact of Events Scale within the first few weeks were more likely to have symptoms at 3 and 6 months. Similarly, McCauley *et al.* (2001) found depression at 1 month was a predictor of post-concussion syndrome at 3 months. Post-concussional symptoms are more often seen in those who are depressed (Rapoport *et al.* 2003) or have symptoms of PTSD (Bryant & Harvey 1999). The role of motivational factors and litigation is considered below.

Pre-traumatic factors also have a role in outcome. In general, the milder the injury and the longer symptoms last, the more likely that constitutional factors will be found to explain who remains symptomatic. Thornhill *et al.* (2000) found that pre-existing physical limitations or brain illness predicted problems at 1 year. However, even as early as 3 months, Ponsford *et al.* (2000) found that the 24% of patients whose lives were significantly disrupted by symptoms were more likely to have a history of psychiatric problem, or a head injury or other neurological problems. Keshavan *et al.* (1981) showed that premorbid 'neuroticism' scores were influential at 3 months. In a study of veterans who were assessed many years after discharge from the military (Luis *et al.* 2003), they were asked if in the meantime they had suffered a mild head injury. A post-concussion symptom complex was more common in those with a mild head injury, especially if associated with loss of consciousness. However, the best predictors of the presence of the post-concussion symptom complex were early-life psychiatric difficulties such as anxiety or depression, limited social support, and lower intelligence. Nevertheless, not all studies find effects of pre-injury emotional factors (Cicerone & Kalmar 1997).

Post-concussion syndrome

A 50-year-old man was referred for assessment 6 years after an injury which had occurred when his lorry was involved in an accident. He had not been rendered unconscious at the time, and indeed the likelihood of trauma to the head had been very slight indeed. He had, however, been exposed to severe emotional shock. During the early months after the accident he had been extremely depressed and lacking in confidence, afraid to meet people and afraid to leave the house.

During the second year after injury he continued to be severely disabled with depression, insomnia and inability to concentrate. His wife described episodes at night in which he would wet the bed, wander from the house, or wake in fear claiming that spiders, frogs and snakes were biting him in bed. She was noted to be excessively overprotective and to smother him with affection. At a medical interview in connection with a claim for compensation it was virtually impossible to get coherent statements from him. He continued to deteriorate, becoming increasingly retarded and vague. Five years after injury it was reported that he could not answer simple questions about his name, age or address. He exhibited a gross tremor of the hands, and his general demeanour now suggested an element of psychogenic elaboration.

Six years after injury he was hospitalised at a considerable distance from his home. Gradually he improved with encouragement. At times he would converse normally, display full orientation and reasonable memory for the events of the past 6 years. During his wife's visits, however, he relapsed into his earlier vague manner, became childishly dependent and expressed irrational fears about being abandoned or subjected to unnecessary operations. By the end of his 4-week stay in hospital it was obvious that he was capable of functioning at a normal level, and comprehensive investigations, including full psychometric testing, failed to reveal any evidence of brain damage. He expressed a desire to return to work, and viewed the previous 6 years as 'blown out of all proportion' and 'being caught up in a network of problems'. Unfortunately, his wife insisted on removing him from hospital before definitive steps could be taken to secure his return to work.

In this case the appearance of severe and progressive dementia proved ultimately to be a response to the psychological trauma of the accident. There was abundant evidence that his wife had colluded and reinforced this aspect of the situation, and in many ways the compensation motive appeared to be more active where his wife was concerned than with the patient himself.

A young professional suffered brief concussion when hit on the head by a falling object; there was no loss of consciousness. She suffered transient dizziness lasting a few days and felt 'spaced out' for about a week with intermittent headaches. Nevertheless, after 5 days she returned to work to a demanding workload. She immediately noticed that she had difficulties concentrating and that working exacerbated her headache. She found it difficult to keep up with her commitments and became increasingly anxious. She suffered a panic attack and at times had depersonalisation experiences. After a month she stopped work and started doing less and less because of symptoms of fatigue and headache when she exerted herself.

By 3 months after the injury she was disabled by symptoms of depression, fatigue, headache and anxiety and was referred for specialist treatment. MRI brain scan was normal. Treatment included telling her company that she would not be returning to work for at least 3 months, an explanation for her symptoms and their prognosis, and guidance on a slow graded return to activities, starting with physical activity. Her activity levels improved and symptoms abated. By 6 months she returned to work part time with strict instructions to her and her employers that she was initially not to work more than 16 hours a week. By 9 months post injury she was working full time with no symptoms.

A journalist fell from a horse and was still unconscious when she arrived in hospital by ambulance. She soon regained consciousness but was vomiting for most of that day. She was kept in hospital overnight and by the next morning was still 'woozy'. Two days later at home she was very disabled by symptoms and in pain. An MRI scan about 2 weeks after the injury showed some evidence of an intracranial bleed. When

she attempted to return to work within a few weeks of injury, fatigue was problematic and she had problems doing two things at once. By 1 year after the injury she was still limited to a maximum of 3 days work a week and notes that 'I feel exhausted much of the time, I am more sensitive to noise and I sometimes have difficulty in doing two things at once' (Sieghart 2000).

These three patients describe three very different stories yet all might have been diagnosed as post-concussion syndrome, at least at some stage during their illness. Therefore the diagnosis 'post-concussion syndrome' may be regarded as unsatisfactory. In the past it has rarely been clearly defined and different authors include different symptoms under the heading. Central to most definitions are headache and dizziness, but to these may be added fatigue, intolerance of noise and light, irritability, emotional instability, insomnia, difficulty with memory, difficulty with concentration or simply 'mental symptoms'. Anxiety and depression are seen in many, and other common emotional symptoms include travel phobia and PTSD. Some patients have marked fatigue akin to chronic fatigue syndrome, and it is possible that the similarities between post-concussion syndrome and the somatisation disorders (Wessely *et al.* 1999) may outweigh any differences between them. Minor degrees of overt intellectual impairment or of change in personality have sometimes also been included, which complicates the picture further. It is not surprising that the concept lacks clarity, and that its aetiology has remained in doubt. Lewis (1942) referred to it as 'that common dubious psychopathic condition – the bugbear of the clear-minded doctor and lawyer'.

The term 'post-concussion syndrome' does not necessarily imply that the head injury was mild. The diagnostic criteria are disinterested as to whether the head injury is mild or severe. However, DSM-IV excludes those with a dementia due to the head injury. It is generally recognised that the symptoms of post-concussion syndrome are more likely to be the cause of disability in a patient after mild head injury than in a patient with more severe injury in whom cognitive impairment and personality change, clearly attributable to brain damage, are the disabling symptoms.

The syndrome may follow injuries of markedly different severity. Numerous different symptoms can be found, cognitive, somatic and emotional, with the pattern varying greatly from one person to another. There is therefore no unique syndrome and some recommend that we employ the term used by DSM-IV: *post-concussional disorder* (Ruff 2005). The criteria used by DSM-IV for post-concussional disorder are stricter than those used by ICD-10 to diagnose post-concussion syndrome (Boake *et al.* 2005). DSM-IV requires 'significant cerebral concussion', symptoms that last longer than 3 months and begin or worsen after injury, and some evidence of cognitive deficits. ICD-10 merely requires a head injury and three or more of eight common post-concussional symptoms.

A second problem is the difficulty linking residual symptoms to the head injury. As noted above, post-concussional symptoms are common in those who have never had a head injury. A further criticism is that post-concussion syndrome is overdiagnosed because some patients with this diagnosis in fact have a collection of symptoms each with their own diagnosis. For example, somebody with dizziness, headache

and irritability might be diagnosed as having post-concussion syndrome, but in fact has a combination of benign positional vertigo, migraine and episodic dyscontrol respectively (Eames 2001).

The diagnosis is also plagued by uncertainty about its cause. When easily demonstrable causes for post-concussion syndrome cannot be found, we are left uncertain how much is physiogenic and how much psychogenic. Some see symptoms as founded in subtle cerebral pathology, while others argue that their roots lie in conflict and anxiety. Much may depend on whether the symptoms under observation are early or late after injury (Lishman 1988). Different populations of patients with post-concussional symptoms will be encountered according to whether they are studied weeks or years after the injury has occurred. Lishman (1988) suggests that organic influences may be operative in the early stages, but that psychogenic mechanisms may often be prepotent when the symptoms are long-lasting. This observation has been confirmed in more recent reviews of the sum total of evidence (Ryan & Warden 2003; Carroll *et al.* 2004b; McAllister 2005). The diverse evidence related to predictors of poor outcome, based on unselected cohorts of patients with mild head injury, has been reviewed above. Here the evidence related to studies on patients with persistent post-concussion syndrome, often recruited from medicolegal practice, is discussed.

Many studies have looked for a physiogenic basis for symptoms in patients with post-concussion syndrome. Those who are symptomatic are more likely to have problems with speed of information processing, and divided and sustained attention, both in the first few months and in the year or two after injury (Gronwall & Wrightson 1974; Leininger *et al.* 1990; Bohnen *et al.* 1992; Chan *et al.* 2003).

Several studies have found changes in cerebral metabolism or blood flow in patients with persistent post-concussion syndrome. Three have looked at ^{99m}Tc -HMPAO-SPECT brain imaging in the resting state. Anterior mesial temporal hypoperfusion (Varney *et al.* 1995), frontal lobe abnormalities (Kant *et al.* 1997), and more widespread hypoperfusion, particularly involving frontal lobes (Bonne *et al.* 2003), have been found. Rates of abnormality on MRI are probably much less, for example 9% abnormal findings on MRI compared with 50% abnormal findings on SPECT in one study (Kant *et al.* 1997). When PET is used to examine glucose metabolism in symptomatic patients with normal structural brain imaging, frontal and temporal abnormalities may be observed (Ruff *et al.* 1994), although this is not consistently seen. Chen *et al.* (2003) found no group differences when comparing five patients with persistent symptoms after mild head injury with five uninjured controls using FDG-PET. However, using H_2^{15}O -PET to measure regional cerebral blood flow, these five patients did have smaller increases in blood flow during a spatial working memory task. Interpretation of these observations on cere-

bral blood flow and metabolism needs to be tempered by consideration of a report of dramatic reduction in mesial temporal and frontal metabolism on FDG-PET in a patient with psychogenic amnesia after psychic trauma but no head injury (Markowitsch *et al.* 1998). Changes in cerebral blood flow and metabolism may be found in depression and PTSD.

Patients with persistent symptoms may show altered electrophysiological responses, including the P50 (Arciniegas *et al.* 2001). The event-related potential to the second of paired auditory stimuli is normally suppressed, but in those with persistent symptoms there was less suppression. There may be changes in other event-related potentials (Gaetz & Weinberg 2000), for example a P300 that is reduced in amplitude and slightly delayed. It has been suggested that delayed brainstem auditory-evoked responses are associated with the development of persistent symptoms (Montgomery *et al.* 1984, 1991), but these findings have not been consistently replicated (Gaetz & Bernstein 2001).

Such observations support the notion of some alteration of cerebral function in those with persistent symptoms after mild head injury. However, if altered cerebral function was the cause of post-concussion syndrome, then one might expect it to be more common in those with severe head injury compared with mild, but the component symptoms lack demonstrable relationship to extent or severity of brain damage (Norrman & Svahn 1961; Lishman 1968). For example, Russell and Smith (1961) showed that longer-duration PTA is associated with more neurological sequelae but did not affect the incidence of anxiety, depression, dizziness sans vertigo and headache. Keshavan *et al.* (1981) showed that whereas the degree of disability was directly related to injury severity, the number of symptoms reported by patients was better explained by psychological factors. Those with mild injury, compared with severe injury, are more likely to have pain and depression (Beetar *et al.* 1996; Kolb & Wishaw 2003). Kay *et al.* (1971) examined patients who had failed to make a good recovery from a head injury. Those without evidence of residual brain damage, i.e. without neurological sequelae, gross personality change or cognitive impairment, were more likely to describe post-concussional symptoms, particularly headache. Furthermore, across those with mild head injuries, some symptoms of post-concussion syndrome are perhaps more common the milder the injury (Lidvall *et al.* 1974).

Non-organic contributions become much easier to discern when patients are still complaining of symptoms after the first few months have elapsed. At 3–6 months after injury, Kay *et al.* (1971) found that psychosocial factors were influential in distinguishing between patients with post-concussional symptoms and those without, i.e. marital status, social class, type of accident and previous history of psychiatric illness. No measure of severity of injury did so. Interestingly, however, as in Rutherford's study, disturbances of vision and anosmia persisting after the acute stages

were commoner in the group with post-concussional symptoms. When persisting beyond 1 year, the evidence becomes overwhelming that such long-lasting post-concussional symptoms in the majority with mild head injury rest principally on psychogenic mechanisms. They figure with great frequency among litigants for compensation (see Compensation, litigation, secondary gain and attribution bias, earlier in chapter, for full discussion of effects of secondary gain, compensation and attribution bias). Symptoms may indeed sometimes set in only after a latent interval following injury, and sometimes the fully-fledged syndrome follows an injury in which there has been no physical trauma to the head but merely severe emotional shock (Walshe 1958). Finally, such symptoms are remarkably rare, as long-continued and disabling features, in the presence of marked intellectual impairment or neurological disability. Nevertheless, as shown in Fig. 4.7, it is important to remain open to the possibility that long-lasting symptoms in those with a mild head injury are due to the direct effects of brain injury.

Thus it may be concluded that the post-concussion syndrome has a complex aetiology in which numerous factors come to play a part. A model is proposed (Lishman 1988) whereby the cerebral dysfunction engendered by head injury, even mild head injury, commonly yields a nuclear group of symptoms, headache, dizziness and fatigue being prominent among them. At the outset these are largely organic in origin, but they are destined to recede by a natural process of healing towards the status quo. If the patient is able to feel untroubled by them, and if left undisturbed by his environment, recuperation will in favourable cases be complete.

However, obstacles to their resolution may arise, and it seems likely that these are mainly of a psychological nature. They may lie in the patient's tendency to worry unduly and to build anxiety around the symptoms, in the handling he receives from those around and the attention he is encouraged to focus on them. Obstacles may arise from other sources of distress: domestic difficulties, resentment about the accident, the need to cope too early or to face an uncongenial job. He may become significantly depressed, and there may be conflict over compensation. What has initially been based in physiogenic disturbance readily thereafter becomes prolonged, and nonetheless disabling, by virtue of a complicated interplay of psychogenic factors. Such a model would appear to apply to the great majority of patients.

Jacobson (1995) presents a more complex model that attempts to avoid a rigid distinction between physiological disorder and psychological disturbance in the genesis and maintenance of symptoms. Cognitive-behavioural factors, including social stresses, personal resources and coping processes, are seen as influential over the entire time course of the syndrome, much also depending on individual differences in sensory sensitivity and psychophysiological reactivity. Analogies are drawn with the large range of factors known to be important in relation, for example, to persistent

pain. Again, the model serves as an important focus around which to explore treatment options in the individual patient. Ruff (2005) concisely summarises the evidence: 'PCD [post-concussional disorder] can be caused by (1) neuropathology, (2) psychopathology, (3) secondary gain in the form of consciously reduced effort or malingering, and (4) any combination thereof'.

Post-traumatic headache

Chronic post-traumatic headache tends to be more troublesome in those with mild head injury than in those whose injury is severe (Alexander 1992; Beetar *et al.* 1996). A significant minority report disabling headache, resistant to every therapeutic attempt, for months and years after injury.

Headache early after injury carries a different prognosis. Headache is present in the majority of patients attending casualty with a mild head injury, but by 48 hours only 52% still complained of headache and by 1 week only 27% (Coonley-Hoganson *et al.* 1984). Lidvall *et al.* (1974) showed the marked decline in headache over the first 3 months. Jones (1974) found that 57% continued to suffer headache, dizziness or both for at least 2 months but the vast majority appeared to be asymptomatic by the 1-year follow-up.

Persistent headache must raise the possibility of subdural haematoma and requires full and careful neurological examination, supplemented by CT or MRI. It may derive from pathology in the upper cervical spine, especially after whiplash injuries. Examination may reveal focal areas of tenderness in the occipital muscles or in relation to healed scalp lacerations. Occipital neuralgia seemed to explain the headache of 10 patients reported by Hecht (2004). The headaches responded to nerve block of the greater occipital nerve. Abnormal vasospastic responses of the arteries of the scalp, or tension headache due to muscle contraction, must also be considered. Friedman (1969) reviewed the numerous theories about the pathogenesis of chronic post-traumatic headache and concluded that there was no specific type.

A more recent review confirms that the exact pathophysiology of headache after trauma is still unknown in many cases (Packard 1999). Commonly, when headache has persisted for many months after injury, no demonstrable physical basis will be discovered. Headache that is diffuse, vaguely described and unremitting throughout the day immediately raises the possibility of a psychogenic basis. The lack of clear precipitants causing it to worsen, and resistance to analgesics, also bias the diagnosis in this direction. Frequently, post-traumatic headache is found along with other components of neurotic disability, and may be noted to fluctuate in severity along with tension or depression. The literature on chronic post-traumatic headache overlaps with that on whiplash injury; whiplash victims make up a good proportion of many cohorts of post-traumatic headache (Martelli, Grayson *et al.* 1999).

Walker and Erculei (1969) analysed the features of post-traumatic headache seen in men 14–17 years after injury. The onset and termination of episodes was usually gradual, and the headache was commonly bilateral and referred to frontal regions. Precipitants, in order of frequency, included noise, nervousness, work, eye strain and lack of sleep. Aggravating factors, in order of frequency, were noise, movement, light, coughing or sneezing and breathing. The descriptions used by the patients were of dull ache, throbbing, pressure, sharp pain or scalp soreness. The headaches were occasionally coupled with nausea and visual disturbances, possibly representing migraine.

Headaches after trauma are rather similar to those seen in patients without a head injury (Haas 1996); 75% were tension type headaches, 21% had migraine without aura and the remainder could not be classified. In comparison to others with chronic headache, but without a head injury, those with post-traumatic headache tend to be more disabled (Marcus 2003; Tatrow *et al.* 2003). This may partly reflect the observation that post-traumatic headache, even in cases of mild head injury or whiplash, seems to be associated with cognitive impairment (Martelli *et al.* 1999).

Dizziness and vertigo

As in the case of headache there is some evidence that dizziness in the absence of vertigo is more common with less severe injury (Russell & Smith 1961). This suggests that dizziness is not merely a reflection of physical injury related to head injury severity, and must be carefully distinguished from true vertigo. Vertigo is probably more common after moderate than mild head injury, and in perhaps 50% of cases, especially if the injury is more than mild, objective vestibular disorder may be found often associated with hearing loss (Berman & Fredrickson 1978). Comprehensive tests of vestibular function may be of value in doubtful cases (Toglia 1969). Harrison (1956) stressed the frequency after head injury of positional nystagmus of the benign paroxysmal type, found in 17 of 108 post-traumatic subjects. However, most of these patients reported a true rotational component to their dizziness, and they were seen within 2 weeks of injury. Care must also be taken to exclude orthostatic hypotension, which may lead to feelings of syncope.

Dizziness that persists for many months will, like headache, often be found to have no demonstrable physical basis. Careful enquiry often shows that it is no more than uncertainty of balance, light-headedness or subjective unsteadiness of gait. It is frequently associated with headache, likewise with other neurotic complaints. The syndrome of 'phobic imbalance', which may be traceable to early vestibular damage but then persists as a disabling neurosis, is described in Anxiety disorders (Generalized anxiety disorders), earlier in chapter. However, dizziness is one of the post-concussive symptoms that best distinguishes patients with a head injury from the general population (Paniak *et al.*

2002b). Furthermore, even though it was associated with psychological distress, dizziness was an independent predictor of failure to return to work at 6 months after mild to moderate injury (Chamelian & Feinstein 2004). This suggests that dizziness should not simply be seen as a marker of psychological problems. In those who complain of imbalance months and years after mild injury, but without vertigo, there may be objective evidence of impairment of postural control (Geurts, Knoop *et al.* 1999).

Whiplash injuries

Whiplash injury results from a sudden unexpected jolt to the body while the head is free to move at the time of impact. The common cause is a road accident collision from behind. There is therefore no warning and since the normal protective reflexes that splint the neck cannot come into operation, the neck is subjected to abrupt hyperextension/flexion or rotational stresses. The result is damage and bruising to the ligaments and other soft tissues of the neck. By any strict definition bony injuries, dislocations or disc protrusions of the spine are excluded, likewise direct trauma to the head.

The condition has attracted a great deal of attention on account of the sometimes prolonged sequelae, which include local pain and stiffness along with considerable invalidism due to headache and nervous complaints. Characteristically such patients become more disabled, and handicapped for longer periods of time, than would be anticipated from the mild character of their accidents. Given that the victim's car is usually stationary when struck from behind, there is almost invariably the possibility of a compensation claim (*res ipse loquitur*). Many patients are soon involved in litigation, and it is often a matter of dispute whether enduring symptoms are determined by organic or psychological factors. When complaints of difficulty with concentration and memory are prominent, it may be further suggested that brain damage has been sustained, despite the lack of any direct trauma to the head.

The immediate sequelae are acute shock and bewilderment, and there may be momentary dazing and confusion. 'Concussion' has been reported in 20–60% of cases, i.e. momentary loss of consciousness followed by feeling stunned and out of contact with surroundings. In many cases, however, it will be hard to judge whether this represents a true impairment of consciousness or a transient episode of dissociation occasioned by stress. Pain and stiffness in the neck, often with headache, develop within minutes or hours, but may be delayed until the following day. In an analysis of 190 acute cases, Balla and Iansek (1988) reported neck ache in 90%, headache in 75% and limitation of neck movement in 50%. Tenderness and spasm of the neck muscles is often severe, with pain spreading to the shoulders and back and into the occipital region. Sharp radicular pain may radiate to the lower jaw, arms and upper anterior chest.

Treatment with rest, analgesics and temporary immobilisation in a soft collar allows resolution of symptoms over the following weeks in favourable cases. The remainder, varying in different reports from 25% to 50% (Radanov *et al.* 1994a), progress to development of *late whiplash syndrome*, in which neck and head pain persist for many months along with symptoms reminiscent of the post-concussion syndrome. The headache is mainly occipital but can be generalised or frontal. It may be dull, sharp or throbbing, and is often accompanied by dizziness. Additional symptoms include prominent fatigue and decreased tolerance to light and sound. Difficulty with sleeping may be due to distressing dreams of the accident. The disability engendered is often remarkably severe, with inability to work and curtailment of social life in as many as 10%. In unfavourable cases the syndrome may persist for several years.

The genesis of this chronic syndrome is open to much uncertainty. Organic components may underlie pain referred from strains to ligaments and the small apophyseal joints of the spine, aggravated no doubt by spasm of the cervical muscles. Disinclination on the part of the patient to attempt gradual mobilisation may lead to a vicious circle of continuing tension from efforts to guard and splint the spine. Much of the psychological distress may stem from the pain and disability engendered in this manner. The possibility that brain damage of a subtle nature may sometimes make a contribution is hard to rule out with certainty. Alexander (1998) concludes that the evidence for brain damage, in the absence of any direct blow to the head, is interesting but not substantive, despite suggestive evidence from animal studies (Ommaya *et al.* 1968).

Possibilities of brain damage are also raised by reports of momentary 'concussion' in a proportion of cases, as already described. An example of amnesia lasting for 72 hours was reported by Fisher (1982).

A woman of 67 was struck from behind while a passenger in a stationary car, sustaining a whiplash injury but no direct trauma to the head. When asked immediately if she was hurt she replied 'What am I doing here?', and proved to be muddled and to have no idea of the purpose of the journey. She was nevertheless fully alert. When examined 2.5 and 10 hours later she was still disorientated and unable to retain any new information. She could not recall anything of the past 4 days and showed faulty recall of the previous weeks and months. She repeatedly asked where she was and what time it was. There was horizontal nystagmus to the left but no other neurological abnormality. By 72 hours after the accident her memory had returned to normal. She could finally recall the car being struck but remained amnesic for the 48 hours that followed. Suggested explanations included shear stresses in the brain or interference with circulation in the vertebral arteries.

However, there has been little else to support the presence of brain damage in the generality of whiplash patients. MRI was normal in the four patients examined by Maimaris (1989). Several studies have examined cerebral metabolism and blood flow using FDG-PET and HMPAO-SPECT respectively in patients with chronic whiplash. One study hinted at the possibility of parieto-occipital abnormalities (Otte *et al.* 1997), but a subsequent more rigorous study suggested that any parieto-occipital changes could be accounted for by differences in cortical thickness as measured by MRI (Bicik *et al.* 1998). Instead, frontotemporal hypometabolism was found that was highly correlated with depression, suggesting it was related to the known effects of depression on cerebral blood flow. Neuropsychological testing has occasionally appeared to uphold the presence of mild brain damage (Bohnen *et al.* 1993). However, poor cognitive performance is associated with high levels of anxiety, rather than changes in cerebral blood flow and metabolism (Radanov *et al.* 1999).

Psychogenic factors are strongly suspected of making an important contribution in many of the prolonged cases. In the first place, symptoms often worsen steadily over several weeks after the accident, which seems inconsistent with organic pathological factors (Gotten 1956). Moreover, psychological sequelae are understandable in terms of the sudden shock attaching to the acute experience, especially since consciousness is usually fully retained throughout. The spasm and tension in the neck muscles may themselves owe much to emotional tension. Mayou *et al.* (1993) found a strong relationship between emotional disorder 1 year after whiplash injury and scores of neuroticism in the premorbid personality.

A few studies have attempted to explore the relative importance of organic and non-organic factors in the aftermath of whiplash injuries. There is good evidence that being female and older are risk factors for chronic symptoms (Cote *et al.* 2001a). Radanov *et al.* (1994b) published a series of studies on up to 117 patients followed up over 1 year. Litigation was not a factor because of the Swiss insurance and legal systems. At all follow-up examinations (3, 6 and 12 months), the outcome was strongly related to the severity of the neck injury, as reflected in initial symptoms of radicular irritation and intensity of neck pain. These proved in effect to be the most reliable indicators of recovery. Other predictors of poor outcome at 6 and 12 months were indicative of the initial reaction to the injury, namely severity of sleep disturbance and scores of 'nervousness', both of which may have been attributable to pain. Better scores across a range of psychosocial measures favoured those with better outcome, though none were statistically significant.

Others have also found that early measures of the severity of neck injury and pain are good predictors of late outcome (Kasch *et al.* 2001; Gun *et al.* 2005; Pobereskin 2005), although estimates of the force of the injury (e.g. as measured by the

speed of impact) are not (Richter *et al.* 2004; Pobereskin 2005). On the other hand, when patients are assessed with a quality-of-life questionnaire early after injury, those who report being more distressed are more likely to have symptoms 1 year later (Richter *et al.* 2004; Gun *et al.* 2005).

The role of litigation will often be thought to be important, and prospective follow-up studies have highlighted the deleterious effects of litigation on outcome (Gun *et al.* 2005; Pobereskin 2005). Among patients seen for medicolegal assessment, Pearce (1989) reported spurious weakness of grip in over half and non-anatomical sensory loss in one-third. Schmand *et al.* (1998) found that patients with chronic post-whiplash syndrome, the majority of whom were in litigation, did badly on a memory test that is in fact very easy even for patients with organic amnesia. The 60% of patients who scored below cut-off on this test also did badly across a range of other tests of cognition. Cassidy *et al.* (2000) studied claims following motor vehicle accidents in Saskatchewan before and after a tort insurance system was changed to a no-fault system. Under the no-fault system the average time to closure of claims was halved to about 200 days. The authors suggested that time to closure of claims was a valid marker of recovery, and therefore claimants recover faster if compensation for pain and suffering is not available. Faster claim closure was associated with a more favourable health status (Cote *et al.* 2001b). However, it is difficult to find the published data on which they base their conclusion that 'recovery from neck pain, physical disability, and depression occurred twice as fast under the no-fault system as under the tort system' (Cassidy *et al.* 2000). On the other hand, some patients remain symptomatic after settlement of all compensation issues (Maimaris *et al.* 1988; Newman 1990), and the chronic syndrome can be seen when litigation has not been at issue.

In Lithuania, where compensation for whiplash is not generally available, surprisingly low rates of chronic whiplash have been reported (Obelieniene *et al.* 1999); 98 (47%) of 210 victims of a rear-end collision, consecutively identified from the records of the traffic police, reported initial neck pain and/or headache. However, by about 3 weeks all had completely recovered from their accident-induced neck pain or headache. The authors argue that in Lithuania there is little notion that rear-end collisions can cause chronic symptoms. Based on this and other observations, Ferrari and Schrader (2001) propose a biopsychosocial model for chronic whiplash syndrome. This account refutes the notion that whiplash is the result of a chronic physical injury, but acknowledges that there were originally, early after injury, physical and psychological sources for the somatic symptoms. They suggest that the driving force behind the development of symptoms is patients' expectation that they are likely to suffer chronic symptoms. Problems are then amplified by the behaviour of professionals and the effects of litigation. As with post-concussion syndrome, attribution also plays a

large part; symptoms that the patient might well have had anyway are attributed to the injury.

Head injuries in sport

Various aspects of head injury in sport have already been discussed in the section on mild head injury, including the time course of recovery of symptoms, the relationship of outcome to loss of consciousness, and the effects of multiple concussions. Post-traumatic convulsions were considered in Acute effects of head injury (Impairment of consciousness), earlier in chapter. The majority of athletes concussed while playing sport have significant slowing of information processing for a few hours after injury, but this has usually resolved after a few days. Ice hockey and rugby have the highest rates of concussion for team sports, but even cheerleaders are vulnerable (Boden *et al.* 2003). Estimates of the probability that any individual athlete will be injured playing ice hockey or rugby during one season are quite diverse, with figures ranging from 3% to 20% (Koh *et al.* 2003). Sometimes even higher figures are quoted, perhaps indicating that it may be difficult to define the lower limit of concussion. High rates of concussion are seen in amateurs as well as professional athletes. In several sports the rules have been changed over recent years to minimise the risk of injury, for example by outlawing dangerous tackles or by enforcement of helmets, and as such lower rates are probably now being recorded (Powell & Barber-Foss 1999). In many sports it is unusual for the injury to be more than very mild, but in horse riding and skiing, and of course motorsports, a higher proportion, though still a minority, will suffer severe head injuries.

Much attention has been paid to guidelines for management in the immediate aftermath of concussion, particularly with regard to whether the athlete should cease playing and for how long. It is hoped that those at risk of further injury can be identified. It might be that continuing impaired coordination and reaction times render them at risk of sustaining further injury. This concern is heightened by the possibility that a second impact following shortly after the first is particularly dangerous. It is also important to identify those at risk of a neurosurgical emergency, for example due to an acute subdural haemorrhage. Validated guidelines on return to play do not exist but the consensus is that symptoms of concussion, both at rest and on exertion, should have completely resolved before the athlete is allowed to resume participation (Johnston *et al.* 2001). Special consideration may be needed for those with a history of multiple concussions and for boxing. Computerised assessments are probably better than pen-and-paper tests at detecting the slight impairments of psychomotor speed which might indicate that complete recovery from a recent head injury has not yet been achieved (Collie *et al.* 2006).

It has been suggested that the occasional person who sustains a second head injury before the symptoms of the first

have fully cleared goes on to suffer catastrophic cerebral oedema, usually followed by death. This *second impact syndrome* is ascribed to a failure of cerebral vascular autoregulation, causing vascular congestion (Bailes & Cantu 2001). The evidence that the syndrome exists rests on only a few case reports. Most of the cases are children or adolescents; it is known that massive cerebral oedema is more common in childhood head injury regardless of any second impact (see below). One review identified only five probable cases in the world literature and suggested there was insufficient evidence to conclude that the syndrome exists (McCrory & Berkovic 1998). Nevertheless, as noted above, all concur that the athlete must be asymptomatic before returning to play. Anybody who returns to play while still groggy is at risk of much more severe injury, for example because of impaired righting reflexes.

It has been noted that in some sports a single athlete is quite likely to experience multiple concussions during their career. The possible cumulative effect of multiple concussions has been discussed above. Indeed the possibility that multiple blows to the head, each insufficient to produce concussion, can cause irreversible cumulative brain injury has been raised by surveys of professional soccer players. A series of studies of retired soccer players found cognitive deficits that were attributed to a history of heading the ball, though with little attempt to exclude alcohol as an alternative explanation. Two studies (Matser *et al.* 2001; Witol & Webbe 2003) found a dose-response relationship between estimates of the number of times footballers had headed the ball during their career and cognitive impairment. In a review of the evidence, McCrory (2003) concludes that head-to-ball contact is unlikely to cause injury, but head-to-head contact, which often occurs as two footballers go to head a ball, might.

Boxing

The question of chronic traumatic encephalopathy in boxers is of special interest, because here serious sequelae appear to follow repeated mild head injuries, each in itself leading to no more than brief concussion. Roberts' (1969) extensive survey, described below, was important in establishing the syndrome as a valid entity, and in providing clear indications that the boxing career had been responsible. The unusual combination of neurological features provides a characteristic picture, and suggests that a distinctive pathological process is responsible. The disabilities usually set in towards the end of the boxing career while the patient is still relatively young. Sometimes the onset is acute and can be traced to a series of particularly hard fights, thereafter dictating retirement. Most examples date from the protracted boxing careers that were pursued before the Second World War when medical control over boxing was less rigorous than at present. New cases are now rarely seen probably because since the

1930s the average number of career bouts has dropped from over 300 to 13 (Clausen *et al.* 2005).

In its fully developed form the syndrome, otherwise known as dementia pugilistica, consists of cerebellar, pyramidal and extrapyramidal features, along with a varying degree of intellectual deterioration. In mild examples there is dysarthria, facial immobility and poverty and slowness of movement. Unsteadiness of gait may not be present, but evidence of asymmetrical pyramidal lesions is common from an early stage. At its most severe there is disabling ataxia, disequilibrium, a festinant gait, tremor of the hands and head, and spasticity or rigidity of the limbs.

Roberts (1969) carefully traced a random sample of 250 professional boxers who had held a professional licence for at least 3 years between 1929 and 1955; 224 were available for examination, of whom 37 (17% of the total) showed evidence of the characteristic syndrome. Approximately one-third of the 37 were judged to be affected severely enough to be recognisable by a layperson as 'punch drunk'. The clinical picture, while varying in degree, was remarkably constant from one case to another. Moreover, the prevalence of the syndrome increased with increasing exposure to boxing as judged from the history. Epilepsy occurred no more frequently than in the general population. The majority of cases remained static once boxing was discontinued. Occasionally, the condition had become more obvious with advancing age, but it was hard to distinguish this from the changes associated with ageing generally. However, undoubted progression was seen in four cases.

Almost half of Roberts' 37 cases showed intellectual and personality changes indicative of dementia in addition to their neurological disablement. This occurred with all degrees of severity. The incidence of personality change was hard to assess, but the boxers' wives often described progressive apathy and irritability with liability to outbursts of temper. Severe paranoid illness appeared to be common, particularly in subjects who showed intellectual deterioration. Johnson (1969) paid special attention to the psychiatric features in 17 ex-boxers with chronic traumatic encephalopathy. The neurological features had usually appeared before the psychological manifestations, and each could then follow an independent course. Four main areas of psychiatric disturbance were apparent: a chronic amnesic state in 11 patients; progressive dementia with disorganisation of intellect and personality in three; morbid jealousy in five; and rage reactions in three. In addition, five patients had shown evidence of psychotic illness.

Studies of boxers in the modern era

The debate now centres on whether the medical controls now in place, and the more limited boxing careers, have rendered boxing safe. In the field of amateur boxing, negative as well as positive findings are found. More worrying evidence is to be found in surveys of professional boxers. The consen-

sus of recent evidence from brain imaging and psychometry is that chronic as well as acute brain damage is still prone to occur, even in comparatively young boxers who are pursuing successful careers. The preliminary observation of Jordan *et al.* (1997) suggests that this is particularly likely in those who are APOE $\epsilon 4$ positive. Of 30 professional boxers, those who were both positive for APOE $\epsilon 4$ and had been in more than 11 bouts were most at risk of neurological manifestations of chronic traumatic encephalopathy.

Neuroimaging

Earlier studies, while giving grounds for concern, suffered from lack of control comparisons. However, more recent studies generally find fewer abnormalities. Jordan and Zimmerman (1988) found no abnormalities on MRI in nine amateurs who had been suspended after knockouts or excessive head blows. In contrast, 7 of 21 amateurs and professionals referred for examination showed white matter changes and focal contusions on CT and MRI (Jordan & Zimmerman 1990). Jordan *et al.* (1992) performed CT brain scanning in 338 active professional boxers. In only 22 (6.5%) was 'borderline' brain atrophy found, and in a further three cases focal low-attenuation lesions were consistent with the effects of previous TBI. There were no definite effects of the number of bouts or knockouts, whereas those with large cavum septum pellucidum were more likely to show atrophy.

The Swedish study of Haglund and Bergstrand (1990) (see below) on former amateur boxers failed to find evidence of brain damage on MRI or CT. However, Zhang *et al.* (2003) did find evidence of cerebral atrophy on MRI in 24 professional boxers as well as evidence of white matter disease both on routine MRI and using DWI to detect higher diffusion constants. Higher diffusion constants correlated with more frequent boxing injuries that required transfer to hospital.

Kemp *et al.* (1991, 1995) have investigated the situation using functional imaging, arguing that by the time CT scans are abnormal the brain damage is likely to be irreversible. In this study, 34 amateur boxers were compared with 34 controls using HMPAO-SPECT, all scans being compared with an 'atlas of normality'. The boxers showed a significantly greater number of perfusion abnormalities than the controls.

Neuropsychology

The 18 boxers tested by Casson *et al.* (1984), of whom 13 were professionals, were without a history of drug or alcohol abuse and had been active only since the Second World War. Neuropsychological testing revealed deficits in several areas of functioning, performance being particularly poor on tests of short-term memory. McLatchie *et al.* (1987) restricted attention to active amateur boxers, aged 18–49 years, and found subtle evidence such as upgoing plantar responses or a degree of manual incoordination, suggestive of brain injury in 7 of 20 individuals; 9 of 15 were impaired on tests of verbal

and non-verbal learning. However, only one had an abnormal CT scan with ventricular dilatation. The presence of abnormalities on neurological examination correlated significantly with the number of bouts fought.

More thorough-going investigations have used carefully selected controls, usually sportsmen from other fields or prospective boxers in training who have not yet been involved in bouts. Here the evidence has sometimes been conflicting. Drew *et al.* (1986) compared young professional boxers with control athletes and found inferior performance on a memory test and on several subtests from the Halstead-Reitan battery that was highly correlated with the number of bouts fought. Ravdin *et al.* (2003) tested professional boxers before and on three occasions within the first month after a bout. Those with high exposure to competitive bouts showed impairment of the normal practice effect on a verbal learning test. In contrast, Levin *et al.* (1987d) found little difference on psychometry between 13 young professionals early in their careers and matched controls involved with other sports. Similarly, Brooks, N. *et al.* (1987b) found essentially negative results on psychological tests in a group of active amateur boxers. However, only half of those invited took part in testing; those refusing may have been subjectively aware of impairments. Moriarty *et al.* (2004) followed over 100 amateur boxers during the course of a boxing tournament during which each boxer had, on average, two bouts. There was no deterioration in cognitive performance as a result of participation in the tournament with the exception of seven boxers whose bout was stopped by the referee, who showed significant slowing in simple and choice reaction time.

Of all neuropsychological tests, speed of finger tapping may be selectively vulnerable. In a thorough investigation of 50 former amateur boxers randomly selected from the boxing register and compared with soccer players and track and field athletes (Haglund & Bergstrand 1990; Haglund & Persson 1990; Murelius & Haglund 1991), the sole difference from controls was on a test of finger tapping. Porter and Fricker (1996) studied 20 amateur boxers and compared them with 20 men who trained in the same gym but did not compete. The boxers were quicker on Trials A and B, but showed slightly slower finger tapping that was if anything worse when followed up, on average after a further 12 bouts, about 16 months later. However, there was no evidence of further deterioration when they were followed up over 9 years (Porter 2003).

Thus, with certain exceptions, surveys would appear to suggest that amateur as opposed to professional boxing is relatively safe with respect to the risk of long-term brain damage. Some findings, however, still raise concern.

Pathology

In those with chronic traumatic encephalopathy, cerebral atrophy is commonly revealed on CT, with dilatation of the ventricles, sulcal shrinkage and sometimes obvious cerebel-

lar atrophy. A characteristic finding is perforation of the septum pellucidum (cavum septum pellucidum), rarely seen in other conditions but occasionally found in otherwise healthy people. It is thought to be a direct result of rupture of the walls of the septum consequent upon recurrent abrupt rises of intracerebral pressure.

At post-mortem, cerebral atrophy and ventricular enlargement are often obvious to the naked eye, and ragged holes may be seen in the septum pellucidum. The most obvious abnormalities are in the deep midline structures, with tearing of the septal region and atrophy of the fornices (Corsellis *et al.* 1973; Corsellis 1989). On microscopy, severe gliosis is seen in such regions, also in the thalamus and hypothalamus. The cerebellum is affected, with gliosis and loss of Purkinje cells. In the substantia nigra there is loss of pigmented neurones similar to that seen in Parkinson's disease.

The cerebral cortex shows extensive loss of neurones, many of those surviving showing neurofibrillary degeneration of the Alzheimer type. Such changes are particularly obvious in the temporal grey matter. However, the senile plaques typical of Alzheimer's disease do not occur. This combination of histological abnormalities forms a pattern apparently unique to the effects of boxing. Additional findings include tearing of axons in the white matter and distorted axonal swellings, also evidence of previous perivascular, meningeal and subpial haemorrhages (Adams & Bruton 1989). The findings by Roberts *et al.* (1990) are of considerable interest. In a re-examination of the material reported by Corsellis *et al.* (1973), using immunocytochemical methods it was shown that though congophilic plaques were absent there was accumulation of amyloid β protein in the brain. All cases with substantial neurofibrillary tangle formation showed extensive immunoreactive deposits of β protein, not congregated in plaques as in Alzheimer's disease but distributed more diffusely. The observation that those who are APOE $\epsilon 4$ positive are more vulnerable to clinical manifestations of traumatic encephalopathy (Jordan *et al.* 1997; see above) lends support to the notion that amyloid β protein deposition plays a part in the pathogenesis.

Helmets and headgear

Wearing a crash helmet may dramatically reduce the risk of head and facial injuries for bicyclists involved in a crash, even if it involves a motor vehicle (Thompson *et al.* 2000). However, this conclusion is derived from case-control studies in which the injuries of cyclists wearing a helmet when involved in an accident are compared with those not wearing a helmet. Head and brain injuries are about two-thirds less in those who wear helmets. However, this result does not necessarily imply that helmets reduce brain injuries. The behaviour of helmet-wearing cyclists is likely to be different from those who choose not to wear a helmet, with the former likely to be more safety conscious and

consequently have less severe accidents. In view of this uncertainty there is a continuing, and polarised, debate on the value of cycle helmets. There is more general agreement that motorcycle helmets are valuable. A systematic review of the evidence, again largely dependent on case-control studies, concluded that they appear to reduce the risk of mortality, and are associated with a 72% risk reduction in head injuries (Liu *et al.* 2004). Helmets were also found to reduce the risk of facial injuries. These favourable effects did not seem to come at the expense of a greater risk of neck injuries. Studies of ice-hockey players also hint at the value of helmets, particularly those with full face-guards, in reducing face and head injuries with no extra risk to the neck (Stuart *et al.* 2002).

In rugby football, the size and type of any helmet is limited by the rules, which effectively only allow the use of soft helmets or headgear. However, it seems likely that this type of headgear is ineffective at reducing the likelihood of concussion. McIntosh and McCrory (2001) randomly selected the under-15 rugby teams of nine schools to wear headgear, whereas the teams from seven schools formed the non-headgear controls. Concussion rates were the same with or without headgear. A laboratory analysis of the impact energy attenuation of rugby headgear showed that they were unlikely to be effective at reducing concussion (McIntosh & McCrory 2000). Likewise, headgear designed to lessen the blow to the head when heading a soccer ball are probably ineffective (Naunheim, Ryden *et al.* 2003).

Head injury in childhood

The after-effects of head injury in children differ from those in adults in certain important respects (Box 4.4). The reasons are to be sought in several different factors. On the one hand, the neural apparatus as a whole appears to be more resilient to damage in childhood. Yet, conversely, certain functions are particularly vulnerable when they are damaged during the course of development. The issues involved, and the complex balance between advantageous and disadvantageous effects when the brain is damaged before maturity, are discussed by Rutter (1993). The social setting of the child is also different to the adult's and will have important influences: the compensation motive is likely to be absent, whereas the cognitive and emotional aftermaths of injury are likely to hamper school work and call forth interactions with the parents that may have important effects.

There is general agreement that the overall incidence of sequelae is lower in children than adults, particularly for mild and moderate injury (Adelson & Kochanek 1998). In physical terms this can partly be attributed to the greater pliability of the skull and intracranial structures in childhood. The pressure effects of the blow will be better absorbed and vessels less readily ruptured. On the other hand, weak neck musculature, a larger head-to-body weight ratio and lack of myelination may all make the child more vulnerable

Box 4.4 Head injury in children

- Shaken baby syndrome present
- Cerebral oedema more likely
- Intracranial haematoma less likely
- Standard measures of injury severity less reliable
- More post-traumatic epilepsy within first week
- Less late post-traumatic epilepsy
- Of those with severe injury the very young probably do worse
- Greater effects of (i) pre-injury status and (ii) family/other psychosocial factors
- Relatively stereotyped personality change of emotional lability, hyperkinesis and reduced attention span, irritability with outbursts or aggression and rage, and impaired social judgement
- Less evidence of post-concussional symptoms
- Potential for more plasticity
- Generally better outcomes after mild and moderate injury
- Strokes immediately following injury more likely

to diffuse axonal injury. Flexion/extension deformity of the brainstem may cause respiratory arrest and consequent hypoxic brain injury; as noted in Cerebral anoxia (under Pathology and pathophysiology, earlier in chapter) this may be particularly relevant to shaken baby syndrome. Cerebral oedema is more common in the young, and it is noteworthy that cases of second impact syndrome, in which it is proposed that catastrophic cerebral oedema follows two Relatively minor head injuries occurring in close succession (see section on sports injury), are found almost always in children and adolescents. On MRI, lesions deep in the brain, for example basal ganglia, thalamus and brainstem, are more common with more severe injuries (Grados *et al.* 2001). However, depth of lesion is not a good predictor of outcome; during recovery children with deeper lesions were able to catch up with their peers with more superficial injuries (Blackman *et al.* 2003). Very young children, less than 3 years old, may be more likely to develop early post-traumatic seizures within the first week after injury (Hahn, Chyung *et al.* 1988). However, children are probably less likely to develop late (after the first week) post-traumatic epilepsy; for example this was found in only 9% of children with very severe injuries requiring inpatient rehabilitation (Appleton & Demellweek 2002).

The powers of restitution and compensation seem to be greater in the young nervous system. However, it is important not to conclude that greater plasticity of the young brain necessarily results in better outcome. The compensatory potential of the young brain in response to focal injuries, as for example used in many animal studies of plasticity, is probably jeopardised in TBI. The diffuse injury of trauma will mean that the areas of the brain that might have taken over new functions are likely to be themselves compromised. Early damage to the brain may also compromise brain

growth (Kolb & Wishaw 2003). For example, there is less growth of corpus callosum after severe TBI in childhood (Levin *et al.* 2000).

Accurate comparisons between groups of child and adult patients are difficult. Though the GCS remains valid for middle and older children, in young children the verbal and eye scores are not easily assessed. The length of PTA cannot be measured accurately in young children, and it is uncertain that it carries the same implications for severity as in adults. Nevertheless, it seems that surprisingly good outcomes are seen in a proportion of children despite days or even weeks of coma (Bawden *et al.* 1985); however, in these children the clinician needs to be alert to the possibility that later development, particularly social development during teenage years, will have been affected. Very young patients with severe injuries are more likely to do badly than older children and adults with equivalent severity of injury (Taylor & Alden 1997; Anderson *et al.* 2000). They suffer a 'double hazard' (Anderson *et al.* 2005) with loss of acquired skills plus interference with further development, such that the child may show little evidence of recovery over time and considerable problems at school (Ewing-Cobbs *et al.* 2004).

The form that residual disturbance takes is also rather different in children. Cognitive disturbances will be influenced by the stage of development that has been reached. While in adults somatic symptoms such as headache and dizziness are the most frequent and long-lasting effects, these are rarely disabling in children. Instead, certain serious disorders of behaviour may be much in evidence, and tend to take distinctive forms.

The greatest problems tend to be seen in those with 'severe TBI, socioeconomic disadvantage, and preinjury behavioural concerns' (Schwartz *et al.* 2003). It is therefore important to evaluate the pre-injury state. Adverse psychosocial factors are not only associated with worse outcome (Anderson *et al.* 2004), but are quite likely to have been responsible for the injury, whether accidental or non-accidental, in the first place (Demellweek *et al.* 2002). Those who suffer non-accidental injury tend to do worse (Prasad *et al.* 2002). The behaviour of the child themselves is also a risk factor. Although the literature is not entirely consistent, it is likely that children who sustain injuries, not just head injuries, are those with more behavioural problems; for example, Bijur *et al.* (1988) found that boys aged 5 with high aggression scores had over twice the rate of injuries over the age range 5–10 years as those with low aggression scores. Children who have suffered multiple mild head injuries show evidence of poorer performance on measures of intelligence (Teasdale & Engberg 2003). However, this is no different from children with multiple injuries but not to the head (Bijur *et al.* 1996), suggesting that the lower IQ was a cause of the multiple head injuries rather than a consequence. Bloom *et al.* (2001) found that despite attempts to exclude children with pre-injury neuropsychiatric disor-

ders, careful inquiry 1 year post injury showed that 35% (16 of 46) had suffered pre-injury psychiatric problems; 10 had attention deficit hyperactivity disorder (ADHD) and six had anxiety disorders. Care is therefore needed before attributing any post-injury intellectual or behavioural problems to the injury itself (Ponsford *et al.* 1999; Donders & Strom 2000).

Cognitive defects have different implications compared with adults, since mental skills are in the process of development. The child stands not only to lose what has already been acquired, but also to prejudice chances of future intellectual growth. In practice profound intellectual disablement appears to be distinctly rare as a result of head injuries. However, occasional examples of severe dementia do occur in children, usually in association with spasticity and other marked neurological defects.

More commonly, the child is observed to be set back only temporarily, and to make good in the months that follow. Recently acquired abilities to walk or talk may be lost, or school work is found to be impaired for a time in relation to his fellows. For a while he may appear to be more backward than is truly the case, as a result of ill-sustained attention, sluggishness or ready mental fatigue. While they persist, however, such factors can hamper education to a serious degree. Behavioural changes are sometimes even more disruptive of progress at school, leading to persistent under-achievement even when no intellectual loss can be identified.

The precise effects of childhood injury on intellectual function are incompletely understood. Clearly, the dynamics of cerebral organisation change during the course of development, so that functions which are crucial at one stage can later be supplemented by others, or deficits which at first remain latent may later be revealed. When considering recovery of IQ after childhood injury it is worth remembering that if the child's actual score on a task remains unchanged over time, this will be registered as a drop in their IQ, because the score of their peers with normal development will have improved.

Chadwick *et al.* (1981) have reported one of the few prospective studies of the cognitive sequelae of head injury in school-age children. Groups of 29 children with 'mild' injuries (PTA <7 days) and 31 with 'severe' injuries (PTA >7 days) were followed with repeat testing for up to 27 months; 28 non-head-injured children served as controls. When the PTA had been less than 24 hours in duration there was no convincing evidence of intellectual impairment, even transient in nature. Others have also shown that children with mild head injury usually have no measurable enduring cognitive deficits (Anderson *et al.* 2001; Teasdale & Engberg 2003; Roncadin *et al.* 2004). However, Chadwick *et al.* (1981) found that deficits were common when the PTA had exceeded 3 weeks, and in some cases could still be detected at the final follow-up examination. In general visuospatial and visuo-motor skills tended to be more severely affected than verbal

skills. Improvement was most rapid during the early months, but further gains were observed for a year and sometimes continued into the second post-injury year as well. A definitely adverse effect on school performance was observed only in children with the most severe injuries, where the PTA had exceeded 3 weeks in duration.

Subsequent studies have further defined the impairments seen (Middleton 2001) and demonstrated that the majority of children with severe head injury will suffer significant effects on their progress at school, on social function, and on cognition (Emanuelson *et al.* 1998; Ewing-Cobbs *et al.* 1998; Max *et al.* 1998a; Teasdale & Engberg 2003). As in adults working memory and speed of information processing, for example as measured by performance on the *n*-back task, is affected in proportion to the severity of the injury (Levin *et al.* 2002; Roncadin *et al.* 2004). Attention and memory are also particularly vulnerable, with the degree of memory impairment correlating with the volume of frontal lesions (Di Stefano *et al.* 2000). Frontal injury also contributes to executive impairment. This common sequela is associated with changes in behaviour (Levin & Hanten 2005), and worse psychosocial outcome (Levin *et al.* 2004). However, compared with adults there may be a greater contribution of non-frontal lesions, compared with frontal, to executive impairment (Slomine *et al.* 2002). This may be because, compared with the adult, the child's brain can compensate for isolated frontal injury, but not if there is in addition more global injury.

Among focal defects, dysphasia has been most closely investigated. A change in cerebral dominance is possible after unilateral brain injury in early life, and this plasticity appears to persist in some degree in later childhood. Communication and social skills are affected, as in adults, by poor understanding of social cues and metaphor (Dennis *et al.* 2001).

Psychiatric sequelae, particularly behaviour disturbances, are repeatedly stressed as the commonest and most disruptive of the sequelae of head injury in children (Max 2005). After both mild (Massagli *et al.* 2004) and severe (Max *et al.* 1998b) head injury, rates of psychiatric illness, particularly oppositional defiant disorder and conduct disorder (Max *et al.* 1998c), are raised. The most common picture is a mixture of restless overactivity ('hyperkinesis'), impulsive disobedience at home and at school, and explosive outbursts of anger and irritability. Marked delinquency may appear by way of stealing, cruelty and destructiveness. Black *et al.* (1969) followed up an unselected cohort of 105 children injured between the ages of 2 and 14. At 1 year after injury approximately 20% of the children showed behaviour disorders that had not been present before. The most disruptive effects on adjustment were produced by hyperkinesis (present in 32% and appearing as a new phenomenon in 15%) and problems with anger control (present in 20% and a new development in 13%). Problems of discipline such as lying, stealing or

destructiveness were a major problem in 10%, and excessive lethargy or passivity had persisted since the accident in 8%. Sleep disturbances and problems with appetite were also occasionally observed. Hyperkinesis was commoner in younger than older children, and behaviour disturbance generally was more frequent in boys than girls. A similar picture, though with higher rates of disturbance, was found by Max *et al.* (2001) studying 37 children with severe head injury; 49% showed personality change with affective instability and the majority of these 18 children also showed recurrent outbursts of aggression or rage, and markedly impaired social judgement. Again apathy and indifference were less frequent, being present in five children (14%).

Brown *et al.*'s (1981) careful prospective study of 50 school-age children demonstrated that the development of new behavioural disorder was related to severity of injury. The group with PTA of less than 1 week showed a raised level of pre-accident psychiatric disturbance compared with controls, but no increase following injury. In contrast, approximately half of those with PTA exceeding 1 week developed new behavioural disorders, this being commoner the more severe the injury. Max *et al.* (2006) also found that injury severity was a predictor for personality change in 177 children with a range of injury severities followed up over 2 years. The proportion of children with a change in personality declined from 22% at 6 months to a stable rate of about 12% over the 1–2 year follow-up period. These 12% were more likely to have frontal injuries and to be rated as having shown worse pre-injury behaviour, but showed no differences on other psychosocial measures. Nevertheless, several studies have demonstrated that the family environment does predict long-term outcome, particularly for behavioural problems (Max *et al.* 1998c; Stanton 1999; Taylor *et al.* 1999, 2002).

Hyperkinesis with reduced attention span is a well-recognised sequela of head injury in children and often fulfils ADHD diagnostic criteria; in a series of 99 children with moderate and severe injury, 20 were found to have antecedent ADHD and 15, when assessed at 1 year post injury, had developed ADHD post injury (Gerring, Brady *et al.* 1998). These 15 children had significantly greater preinjury psychosocial problems, and were more likely to have other behavioural problems, than those without ADHD. Though there was no significant effect of injury severity, as measured by lower IQ, other studies have demonstrated that new onset ADHD is more likely in those with more severe injury, and have confirmed the association with preinjury factors (Gerring *et al.* 1998; Max *et al.* 1998d). Children with secondary ADHD are not only more likely to have suffered a severe injury but, as in ADHD in the absence of head injury, also show response inhibition on a stop-signal task (Max *et al.* 2004).

Whatever its origin, post-traumatic behaviour disturbance can have serious consequences in terms of school

achievement, which may be markedly impaired despite good preservation of intellect on formal testing. Hill (1989) discusses the serious impact that personality changes after severe head injury can have on schooling and social development; blunting of emotional responsiveness may make continuing social education extremely difficult, and loss of tact and judgement may lead to social isolation, particularly in adolescents. Considerable adverse effects on personality may accrue from changes in self-appraisal and self-identity during a vulnerable phase of development. Turning to other psychiatric sequelae (Max 2005), PTSD is occasionally seen after childhood head injury. Children with depression or anxiety after head injury have often had these symptoms before injury. Psychosis is a very rare consequence, and it is interesting to note that autism seems to be absent after head injury.

Although parents tend to report problems with conduct and attention after head injury, it is, if anybody, the injured children themselves who report post-concussional symptoms in the early weeks after mild to moderate injury, similar to those described by adults (Mittenberg *et al.* 1997). Persistent disabling post-concussion syndrome is not a recognised sequela of mild head injury in childhood. However, one study has found that, compared with children with fractures to the legs, children after a mild head injury report more headaches, dizziness, fatigue and memory problems 2 years after injury (Overweg-Plandsoen *et al.* 1999). However, these findings run counter to clinical experience that headache is rarely prolonged and that dizziness is likewise very rare after injuries early in life.

Medicolegal considerations

The majority of head injuries result from either road traffic accidents or accidents at work and therefore frequently become an issue before the courts. Motor insurance covers road traffic accidents, and personal accident insurance covers many accidents which occur in other settings. Legal problems may involve the proof of prime responsibility or of negligence. With industrial injuries the employee will need to show that the employer was negligent or in breach of a statutory duty. The no-fault system operative in New Zealand has attracted considerable interest, in that injured persons have no need to take legal action. Instead there is a statutory body, with responsibility for compensation, rehabilitation and accident prevention.

Whatever the setting of the accident, a medical report usually comes to form an important part of the proceedings. However, psychiatrists should probably decline requests from solicitors to write reports on patients they are treating. It can be difficult for the doctor to marry the requirements of the court report, with its demand for a disinterested approach, with his/her therapeutic alliance with the patient. It is usually better to appoint an independent expert witness.

The defendant in the case, usually an insurance company, will often wish to seek another independent opinion. In some instances the doctors from the two sides meet and agree on a report for the court, but this is not always the happy solution. Legal proceedings may become burdensome and prolonged. Nevertheless, in the interests of justice to all parties the situation must be accepted, and a proper skill in the presentation of evidence must be acquired.

The court will need to make its decision on three main aspects of the situation where the medical evidence is concerned: (i) on the nature and degree of disablement that has followed the injury; (ii) on the likely duration and future course of such disablement, and the impact it will make on the quality of the patient's life; and (iii) fundamental to all the rest, the causative relationship between the disability and the injury which preceded it. All three can in some circumstances be the subject of uncertainty and open to argument.

Nature and degree of disablement

The nature of the disablement and its severity are decided from clinical examination, supplemented wherever possible by objective test procedures. With many areas, however, it is necessary to depend largely on the patient's own account, that of his friends and relatives and sometimes that of his employers. Evidence from observation in hospital or rehabilitation units is invaluable, since the other sources can hardly be expected to be free from bias once litigation is under way. Very important information can often be obtained from the records of the patient's general practitioner, particularly where premorbid levels of functioning are concerned.

All too often it is necessary to accept unsubstantiated evidence and to make a reasoned interpretation of its reliability. Evidence of altered disposition or of emotional instability, for example, must often be derived from accounts of behaviour furnished by others. The situation can be particularly difficult when subjective complaints form the main burden of the patient's disability, as with persistent headache, dizziness, fatigue or inability to concentrate.

The impression made at interview, and equally that made before the court, can be misleading in both directions. The patient with intellectual impairment or frontal lobe damage may cheerfully disclaim any symptoms whatever, and the likely impact of the injury on his life may be revealed only by an informant, skilled examination or psychological testing. Conversely, the patient may greatly exaggerate his symptoms, and claim unfitness for work or inability for enjoyment when objective evidence of disability is slight.

As noted earlier (see effects of compensation, under Compensation, litigation, secondary gain and attribution bias, earlier in chapter), a diagnosis of deliberate simulation must be made with extreme caution. Careful note should be made of the patient's attitude to detailed history-taking, and of any striking inconsistencies which emerge. For example, the vigour with which he pursues the claim and the detail with

which he recounts events connected with it may be at variance with his complaints of torpor, failing memory or difficulty in sustaining concentration. His appearance may belie complaints of insomnia or constant headache. The medical advice that the patient has sought in the interim, and the regularity with which he has attended and followed the treatment prescribed, may also give important indications of the true extent of his suffering. It is fair and just to tell him on occasion of conflicts in his evidence, and to reassess this further in the light of his response and explanations.

Estimate of prognosis

The question of prognosis will certainly be considered by the court. Here it is usually possible to do no more than give a reasoned expectation and to be frank about the measure of uncertainty which surrounds it. It could be argued that after head injury of any severity the patient's condition is never likely to reach stability, and that full justice could only be met by a lifetime's follow-up (Miller 1969). In practice, however, a compromise must be accepted, since compensation is likely to be paid as a lump sum on the basis of shorter-term assessment, usually within 2–3 years of the accident, together with prediction of the likely future course.

Follow-up studies of patients coming before the courts, which would help estimation of prognosis, are remarkably few. However, here the frustrating delays which so commonly attend legal proceedings can sometimes prove to be an indirect advantage, especially when the patient has remained under regular surveillance and when repeated detailed examinations have been carried out. Even severe post-traumatic dementias are known to be compatible with improvement over long periods of time, and serial testing may already have indicated the course that is likely to be followed in the present instance. Moreover, a truly confident prognosis can sometimes only be given when the patient has returned to work. Examination may have failed to reveal much in the way of intellectual loss, yet impaired judgement and irresponsibility may later prove to make him totally unsuitable for his former occupation.

On the other hand, where the compensation motive is suspected to be active, it may be felt that until litigation is ended the future course will remain uncertain. If the compensation issue is thought to play a part in determining the prolongation of symptoms, this should be clearly stated in the report. However, sometimes it is better not to venture too firm a forecast but merely to state the uncertainties which surround the patient's future course. It is the decision of the court which will be operative, and where present medical knowledge is insufficient to help in this decision it must not be allowed to bias it unfairly.

The question of post-traumatic epilepsy should be considered in every case, and when epilepsy has not already occurred the possibility of its future development should be kept in mind, given the possible impact on future disability.

Other possible late effects of head injury – post-traumatic parkinsonism or the development of multiple sclerosis or Alzheimer's disease – are probably too rare and too controversial to warrant mention unless they have already made an appearance.

In all questions of prognosis, and particularly where mental symptoms are concerned, the patient's age, general physical and mental health, and the intelligence which he may bring to bear on adjusting to his disability should be fully considered. The court will strive to make a just award on the basis of loss of earnings and impairment of the quality of life to be followed, rather than on the actual severity of individual symptoms. Therefore the social setting must also be carefully evaluated. For example, the patient who relies on his intellect for pursuing his career may be especially handicapped by even slight disturbance of cognitive function.

Relationship to injury

With regard to the causative relationship between the injury and the disability that follows, we are liable to find that the further we move away from purely physical disabilities, the more causation is likely to be open to question. Cosmetic, orthopaedic and neurological defects can usually be directly blamed on the injury, but psychiatric sequelae with their multifactorial aetiologies can raise very special problems.

The physician must not always expect to find a strict concordance between what is accepted as causal medically and what is viewed as causal in the legal sense of the term (Trimble 1981). The medical definition of causation embraces all the things which have contributed to the result, not only the proximate events but also pre-existing conditions such as special vulnerability in the individual. On the other hand, the juridical definition of causation is almost wholly absorbed in whether some specified event, in this case an injury, can be shown to have contributed to the result.

This is particularly important for consideration of predisposing factors. What is of interest to the court is whether a similar result could have occurred with a high probability at any time or in other circumstances, even had the injury not occurred. Thus a patient long subject to recurring neurotic disability may receive scant sympathy from the court when injury is seen to lead once more to a situation which has often occurred before. The correctness or otherwise of such views could be the subject of long debate. However, it is the legal decision which carries force, and the duty of the medical referee is to place before the court the sum total of evidence in the individual case.

When complicating factors follow injury the court will similarly need to decide what weight to put on them. Sometimes the injury will be seen to have set in motion a whole chain of circumstances that contribute towards the psychiatric disability. Thus the break-up of a marriage or the loss of a

career may be traceable directly to the injury, and may be factors of great importance in prolonging affective disorder or neurotic forms of reaction. The injury itself may have been mild, even when repercussions have been severe. On the other hand, independent intervening life events, e.g. the death of a spouse from cancer, may need to be considered in terms of their contribution to psychiatric disability.

It is therefore essential for the physician to formulate all aetiological factors that have a clear bearing on the case, in addition to the restricted role of the trauma itself. Unfortunately, in the determination of psychiatric sequelae, some of the contributory factors will be idiosyncratic to the individual concerned.

Finally, when the clinical picture agrees closely with what would have been expected from the severity or location of known brain damage, this concordance should be stressed. For example, egocentricity, irresponsibility or coarseness of personality will be more readily attributed to head injury when damage has involved the frontal lobes, even if the pre-morbid personality was poorly integrated beforehand. Similarly, the auras of post-traumatic epileptic attacks may conform to the site of penetrating injury, and confirm that a new disorder has been produced even though the patient has experienced epilepsy before.

The court report

A first essential in undertaking examinations for the courts is to obtain the patient's consent for the report to be sent to the solicitors who request it. Adequate time should be devoted to the interview and examination, or to a series of examinations if these are indicated. Full notes must be kept of all the information obtained since medical documents may be called before the court. Bell (1992) gives detailed advice about the evidence to be gathered and the preparation of the report.

Time should be spent in obtaining the fullest possible information about details of the injury itself, from which to judge the likely severity and distribution of brain damage. The duration of unconsciousness, confusion, RA and PTA should be carefully assessed, along with the extent of early neurological defects. Complications such as skull fracture, raised intracranial pressure, blood in the CSF, haematomas or intracranial infection should be noted, also early episodes of fainting or other transient disorders that may prove to be the prelude to post-traumatic epilepsy. Drugs, particularly analgesic and sedative, administered in the early days after injury should be documented; they may prolong the period of reduced conscious level so that if their effects are ignored the severity of injury may be overestimated.

Any deficiency in investigations which come to light should be remedied. Careful psychometric testing is almost always needed. It is rarely possible to compare the results of psychological testing with results obtained before the injury

occurred, but valuable interpretations can often be made when results are judged against previous educational and occupational attainments. The results of psychological testing should not be given unbacked by the general clinical impression of severity of impairment, since dementia may be manifest in behaviour and personality deterioration as well as in cognitive dysfunction. Some understanding of the psychological test methods used to detect poor effort or malingering may be required. MRI scanning may be needed.

The report should embody the date and place of examination and specify the length of contact with the patient and his illness. Additional sources of information that have contributed to the material in the report should be listed: reports from informants, general practitioners and other hospitals, and the results of special investigations performed. The patient's symptoms and all objective evidence of deficits should be described in detail, and only thereafter should any tentative opinion be expressed about the reliability or otherwise with which the patient's complaints can be taken to represent the true state of his disability. In other words, full descriptive evidence should always be presented before matters of interpretation. The question of prognosis should be handled with caution, and expressed in probabilities rather than certainties.

Finally, the formulation of aetiology will embrace the likely role of trauma in relation to the picture presented by the patient, together with such constitutional and other antecedent circumstances that may have conferred special vulnerability. In cases where there is evidence of antecedent vulnerability it may be useful to consider the likely natural history of the patient had the injury not occurred. Where causal chains of circumstances have followed in the wake of injury and added to the disability, these should also be clearly and simply explained. Full supporting data must always be given to help define the contribution due to injury and that due to other additional factors.

The report should be as concise as possible and should avoid technical jargon, or where this is inevitable a simple explanation may need to be included. It is sometimes necessary to bear in mind that the patient may himself have access to the report, although this should not be allowed to dictate any alteration in material content. Finally, it is perhaps worth mentioning that in the interests of justice it behoves doctors to re-read their reports with scrupulous attention to the overall impression that it makes. Their evidence will have a powerful influence, even though the final decision regarding compensation will be made by others. It is all too easy for the doctor to identify with the patient's wish for compensation, especially when this is to be forthcoming from a large impersonal body. Conversely, when the patient has been importunate, dilatory or difficult to treat, a careful re-reading of the report may indicate that the writer has come to be unfairly biased against him.

Rehabilitation and psychological therapies

The treatment of the acute stages and early complications of head injury are not dealt with here, nor the important matter of prevention of head injuries. Nevertheless, it should be noted that clinicians are well placed to inform the public and government about the consequences of head injury and the value of measures aimed at reducing the risk of head injury.

Early management

Prevention of post-concussion syndrome

Guidelines for management of head injuries in the accident and emergency room of a severity that may or may not require admission tend to focus on early detection of neuro-surgical complications. What is often lacking is guidance for the patient with less severe injury on how to manage over the days and weeks that follow, back at home and trying to get back to work.

The majority of patients with mild head injury are going to do well without any intervention and, for example, early enforced bed rest of a few days is probably not helpful (De Kruijk *et al.* 2002b). Strategies to identify patients at high risk of problems may be useful. Wade, King and colleagues, using randomised controlled trial (RCT) methodology, demonstrated that there was not much value in offering additional information, advice and support 7–10 days after injury to all patients with mild head injury (Wade *et al.* 1997). However, for those whose injury was severe enough to require admission to hospital this intervention did reduce post-concussional symptoms and social disability at 6 months (Wade *et al.* 1998). Others, using similar strategies aimed at providing guidance on how to manage symptoms, have found similar effects (Mittenberg *et al.* 1996; Ponsford *et al.* 2002). It seems that a single session of assessment and advice may be sufficient (Paniak *et al.* 2000).

Early rehabilitation for severe injury

Rehabilitation should be planned and supervised with care from the early stages of recovery. The initial convalescent period is usually undertaken in hospital, and ideally in an atmosphere as free from stress as possible. Physical activity should be encouraged, provided certain limits are imposed, and the value of early mobilisation has come to be generally recognised (Lewin 1968). Graduated exercises and games help to restore the patient's physical self-confidence, and morale is improved by opportunities for social interaction. It is essential that the patient and family know that a full assessment has been made of any possible damage to his brain, and feel confident that the advice given is soundly based. Time devoted to exploration of anxieties is always well spent. However, early estimates of prognosis should be given cautiously, offering a broad window of possible outcomes.

Explanation should be given about residual symptoms at an early date – fatigue, mental slowing, headache, dizziness – but difficulties not already present should not be implanted in the patient's mind. Depending on the severity of the injury, strategies for return to work or for more intensive rehabilitation, possibly in a residential unit, will need to be considered. The first step must always be the systematic evaluation of residual disabilities and assessment of the causes operating in the individual case.

Neurological sequelae

The main areas that require evaluation are locomotion, upper extremity function and impairment of communication. Visual acuity and visual field defects must also be assessed. Hemiparesis requires physiotherapy when more than mild and transient, similarly paraparesis or ataxia of gait. Occupational therapy has a special place in restoring useful function to the upper limbs, and speech therapy in assessing that food and drink can be safely swallowed and in helping the resolution of dysphasia or dysarthria. When treatment is undertaken in hospital or in rehabilitation units the nursing staff can contribute usefully in these areas, likewise the relatives when patients are treated on an outpatient basis.

Cognitive impairment

Full psychometric assessment is a first essential, and serves to highlight both areas of deficit and areas of preserved function on which to capitalise. Memory functions are of crucial importance and should be comprehensively evaluated from the outset.

Some general principles should underlie the planning of the therapeutic programme. First, the confidence, and where possible the full cooperation, of the patient must be secured. The relatives also must be kept informed of aims, progress and necessary limitations. Second, an optimistic and positive approach is required in order to instil enthusiasm, with ready allowance for fatigue and tolerance of shortcomings. The personalities of the therapists can therefore be of great importance. Third, the programme must be graded, with goals at any stage that are realisable, rational and acceptable to the patient (Wilson *et al.* 2002). Self-esteem is bolstered by the setting of tasks that can be mastered, however simple these may need to be at first. Success then serves as a catalyst which encourages and maintains endeavour. The tasks must also be suited to the patient's needs and inclinations. Finally, throughout the course of rehabilitation careful attention must be paid to basic matters such as the maintenance of optimal physical health. It is vital to detect depression, and to make due allowance for matters of personality change as well as intellectual impairment.

Reviews of the efficacy of cognitive rehabilitation suggest that some treatments may be effective (Cicerone *et al.* 2000). However, there has been a tendency to concentrate on outcomes that are closely linked to the intervention, for example

a measure of speed of information processing in a study aimed at improving attention, rather than outcomes that patients themselves will be aware of, for example in terms of improved quality of life or reduced handicap (Carney *et al.* 1999). It is important to use outcome measures that as well as being reliable are relevant to the patient or carer (Fleminger & Powell 1999).

To understand the targets of rehabilitation it is useful to consider the framework of the World Health Organisation International Classification of Impairments, Disabilities and Handicaps (ICIDH) (WHO 1980). Whereas *impairment* refers to the direct effects of the disease on physiological or psychological performance, *disability* refers to the consequences of impairments on the ability of the person to undertake activities. *Handicap* extends the concept of disability to take into account the fact that the social effects of a disability may depend heavily on the person's circumstances. An example of this latter effect is the dramatic differences in handicap experienced by a professional violinist compared with a right-handed painter, when both suffer the same disability due to a left hemiplegia.

Cognitive rehabilitation can be broadly categorised into those strategies that attempt to reduce the impairment and those that attempt to reduce the disability and handicap through compensatory techniques (Ylvisaker *et al.* 2002). For example, in patients with amnesia, rehabilitation might aim to reduce the degree of memory impairment by the use of memory exercises or drills aimed at improving memory, or it might look at compensatory strategies to help them cope with memory impairment and enable them to remain independent at home. Compensatory strategies could include electronic memory aids, errorless learning strategies, mnemonics, and cooking with an electric cooker with a timer rather than gas. A good example is Neuropage, an electronic paging device that is programmed according to the needs of the individual patient to beep several times during the course of the day to remind the patient to undertake various activities. This was found not only to reduce memory failures but to improve planning (Wilson *et al.* 2001). Such compensatory techniques are readily aligned with goal planning, which almost invariably forms the basis for planning and implementing rehabilitation. The research evidence suggests that rehabilitation aimed at reducing cognitive impairments may not be as effective as techniques aimed at improving disability and handicap (Wilson 2002).

It is sometimes argued that rehabilitation does not necessarily require a full theoretical understanding of the psychological processes underpinning the cognitive function that is impaired; and that a simple functional analysis of the consequences of the impairment is adequate to guide the rehabilitation strategy to be used. Evidence in support of this was presented in a meta-analysis examining studies aimed at improving attention (Park & Ingles 2001). Attention retraining techniques typically involve repetitive exercises or drills

requiring a response to visual or auditory stimuli and are often informed by the theoretical ideas of cognitive neuroscience. These were compared with approaches that concentrated on helping the patient with attention deficits to perform specific functional skills. The latter approaches were generally found to be more effective. However, theory-driven rehabilitation may be effective, as demonstrated in a study to improve problem-solving skills (Hewitt *et al.* 2006). An autobiographical cueing system, in which patients are prompted to think of specific examples from memory of when they did something similar in the past, was shown to be effective. This intervention was derived from research on executive function. However, it must be admitted that the dysexecutive syndrome is often very difficult to treat, probably because it is often associated with limited insight.

Behavioural disorder

Strategies for managing behavioural problems after brain injury will usually go hand in hand with the methods described above for managing cognitive impairment. Services for head-injured patients need to be able to address all areas of difficulty, including emotional problems. Techniques derived from cognitive therapy, aimed at helping the patient alter maladaptive patterns of thinking, may be needed. However, programmes of treatment aimed at improving behavioural problems tend to rest heavily on techniques involving reinforcement or inhibition of specific behaviours. Such behaviour therapy is particularly relevant to those with severe cognitive impairment, or with poor insight or poor motivation.

Behaviour therapy starts with a behavioural analysis. A baseline diary is kept to document the frequency of behaviours, as well as their antecedents and consequences. In this way the therapist can draw up a programme aimed at reducing the occurrence of situations that trigger the behaviour and the responses of others that seem to reinforce it. Many models of behaviour therapy are based on the assumption that social interaction is a potent reinforcer of behaviour (Hollon 1973). Antisocial behaviours are therefore easily reinforced because of the attention they evoke. This results in learned maladaptive patterns of behaviour that are best treated with programmes based on ignoring the challenging behaviour. Imposed periods of social isolation ('time out') may also be required, or abrupt 'on the spot' withdrawal of staff attention ('time out on the spot', also known as TOOTS), all against a background of positive reinforcement when things are going well. Thus more constructive responses are shaped and encouraged using differential reinforcement of other (DRO) behaviour (Hegel & Ferguson 2000). Other strategies to be considered include star charts, with rewards being gained for absence of unwanted behaviour. Some units use a token economy regime carefully adapted to the circumstances of each individual patient. Tokens are earned or forfeited in relation to key aspects of the day's behaviour, then exchanged for privileges within the unit. To be effective these techniques must be implemented in a unit where all the staff are trained to provide a consistent approach (Eames & Wood 1985). Though there have been no RCTs demonstrating the efficacy of such behavioural programmes,

well-controlled single case studies provide convincing evidence that they work, at least in some patients (Alderman *et al.* 1999).

Once behaviours have come under control in a particular setting it will be necessary to ensure that the success can be generalised to other, probably less structured, settings. This is likely to involve working with the family and carers so that they understand the principles involved, e.g. in order to reduce the risk of reinforcing unwanted behaviours. This may involve educating the family about the potential deleterious effects of expressed emotion and the importance of providing a non-confrontational ambience that is predictable and supportive. Patients are likely to do badly in a turbulent setting where carers and family vacillate between displays of affection on the one hand and critical comments and anger on the other. Psychotherapy at a relatively superficial level can be of benefit if a working relationship can be established. It should aim at helping the patient to achieve some insight when this is lacking, at least into the more disturbing aspects of his behaviour. A measure of control may sometimes be achieved in such matters as disinhibition, impulsiveness or emotional outbursts, though progress is usually limited. Discussion can also usefully centre on problems that arise day to day in consequence of the patient's altered disposition, and here group therapy may be effective (Delmonico *et al.* 1998).

Short of such decisive intervention, much may still be required by way of clinical surveillance. This may be particularly the case for patients with personality disorder, this usually being resistant to psychological treatment. In many patients there will be enduring concerns about their safety and the safety of others. When irresponsibility is a marked feature, close supervision may be needed over matters of finance, and the patient's family must be brought fully into the picture. Indeed post-traumatic personality change is often the area in which the relatives most require advice, explanation and support. Ongoing contact with a social worker or case manager can prove invaluable in helping to avoid domestic, financial and occupational crises.

Rehabilitation services: from post-traumatic amnesia to return to work

Head-injured patients often present a combination of physical handicap with disturbances of intellect, mood and behaviour. They are therefore liable to fall between the two stools of adequate provision for physical therapy and adequate facilities for psychiatric supervision (Lishman 1983). Properly organised rehabilitation units allow a multidisciplinary approach, both in evaluation and in the supervision of treatment. Neurologists, rehabilitation physicians, psychologists and psychiatrists may need to work together alongside physiotherapists, occupational therapists, speech therapists and social workers. Exactly what services are needed for the individual patient will be determined by the

severity of injury, the nature of the sequelae and the stage of recovery.

Inpatient and day-patient intensive rehabilitation

For those with more severe disability a period spent in a rehabilitation unit is often valuable for assessing the full extent of the patient's difficulties and limitations, and may help towards the elimination of socially disruptive behaviour. If possible this should take place as soon as the patient is medically and surgically stable. If patients remain on the medical or surgical ward, they are likely to get bored, frustrated and agitated and to need sedation. Transfer to a rehabilitation unit may therefore be an important step in preventing behavioural problems escalating. Depending on the nature of the patient's disability, it may be more appropriate to arrange transfer to a specialist neurophysical rehabilitation unit. On the other hand, a unit for patients with cognitive and behavioural problems may be more suitable, particularly if there are problems with insight and reduced safety awareness, as often found in these early stages.

It has been suggested that such interventions, delivered early, will reduce subsequent disability and indeed pay for themselves as a result of reduction in subsequent health-care costs (Cope & Hall 1982). Many units take a holistic approach, embedding cognitive rehabilitation in a therapeutic programme that addresses all aspects of recovery including the behavioural and emotional sequelae (Prigatano *et al.* 1984; Ben-Yishay *et al.* 1985). One study found that even among severely injured and behaviourally disturbed patients who would normally be considered to have a poor prognosis, intensive rehabilitation can be effective (Burke *et al.* 1988). The majority had been unconscious for over 6 weeks and showing evidence of diffuse or frontal brain damage. Almost 90% had been referred because of emotional and behavioural problems, and one-third were admitted directly from secure psychiatric settings. Follow-up 3–12 months later showed that half were living independently, and half were maintaining successful employment, albeit often in supported settings.

Therefore intensive rehabilitation seems to be effective for some patients. However, the only RCT to evaluate inpatient cognitive rehabilitation found that, for the majority of patients after a moderate to severe head injury, a low-intensity home-based programmes was as effective (Salazar *et al.* 2000). It must be acknowledged that a select group of patients was studied; they were all active-duty military personnel with family support. For those with more severe injury, unconscious for more than 1 hour, the inpatient programme did seem to be more effective. Therefore for many, particularly if support is available at home, rehabilitation in the community is appropriate. On the other hand, some will need inpatient cognitive rehabilitation, particularly those with little safety awareness, behavioural problems or limited support at home. Some of these patients will need to move on to a transitional living unit, a halfway house, so that they can

improve their independent living skills in a more demanding setting, before finally returning to live in the community.

Community rehabilitation and return to work

For those living in the community, rehabilitation often works best if the therapist goes to the patient's home. This makes it easier to ensure that therapy is tailored to the patient and his situation. One RCT has shown that such outreach programmes are effective at reducing disability even years after injury (Powell *et al.* 2002). A goal-planning approach is likely to be used, with most goals getting the patient doing more with less support. Some of the action plans to achieve these goals will require one-to-one support, with a therapist or care worker being with the patient for perhaps a few hours a day. Others will require independent work both within the home and outside. Setting a structured timetable to the week is likely to be a crucial element. Once reasonable independent living skills have been mastered, strategies to look at return to work will be an important consideration for many patients.

An essential part of rehabilitation lies in the help and guidance offered when the time comes for preparation for return to work (Yasuda *et al.* 2001). The strategies to consider when post-concussional symptoms are present are discussed in the next section. However, the ideal of return to the original occupation may have to be changed on account of persistent physical or mental handicaps. In practice the chief hindrances usually prove to be of a psychological kind: poor timekeeping, inadequacy of memory, slowness and weakness of attention, early fatigue, irritability and poor social judgement. Therefore a thorough assessment will be needed to ensure that employment targets that are reasonably achievable are selected. Sometimes specialist return-to-work programmes will be needed. These are usually day programmes to mimic the demands of getting to work daily (Box 4.5). In the longer term, job retention is as important as getting back to work. Those who are unable to manage under ordinary working conditions may need entry to a sheltered workshop or day centre. Alternative targets include unpaid work such as homemaker, volunteer or student.

McMillan *et al.* (1988) argue for the benefits of introducing case management for severely head-injured patients. A designated case manager should be in a position to establish a continuous link among the various service providers, build up knowledge of what is available locally, and coordinate input to the patient and the family. However, RCT evaluation of the usefulness of such a role in the UK has given inconclusive results, largely it seems because of difficulties in augmenting contact with the scarce rehabilitation services available (Greenwood *et al.* 1994).

Post-concussion syndrome

Treatments to thwart the development of post-concussional symptoms have already been discussed. There is less research

Box 4.5 Components of a vocational rehabilitation programme (Yasuda *et al.* 2001)

- Training to secure prerequisite stamina, work competencies and behaviour, and productivity levels
- Job development and analysis to identify which jobs are likely to be most suitable
- Placement in a supportive employment setting with a job coach to improve the individual's stamina, work competencies and behaviour, and productivity levels, and to identify problems (e.g. for 3–4 months)
- Substantive job placement in which job coach/counsellor provides support to secure employment through working with the employer and person with TBI
- Short-term support and long-term follow-up in which job coach/counsellor provides limited, on-the-job support and follow-up by phone

evidence to guide the treatment of symptoms once they have become persistent. Most would agree that a thorough evaluation aimed particularly at understanding the contribution of brain injury, and in addition other causative factors, is the foundation for a therapeutic alliance. Education about the aetiology of symptoms will follow. This will pay particular attention to the possibility that psychological factors can result in physical and cognitive symptoms; much can be learnt from the reattribution model used in somatisation disorder (Goldberg *et al.* 1989). Patients also need to understand that management is the same regardless of whether symptoms are due to brain injury or psychological processes; there is therefore no value, in the face of a normal MRI, in an endless search for conclusive evidence of brain damage. Once the possibility of brain damage has been fully assessed, further physical investigations are best kept to a minimum. A preliminary study of the effectiveness of cognitive-behaviour therapy for persistent post-concussional symptoms is encouraging; 11 patients randomly allocated to 3 months of cognitive-behaviour therapy suffered less psychological distress at the end of treatment than the nine patients allocated to waiting list control (Tiersky *et al.* 2005).

A key issue may be return to work. Symptoms will often have deteriorated alongside attempts at returning to work, and the patient is likely to be troubled because the pressure to return to work quickly conflicts with the need to allow symptoms to resolve, sometimes quite slowly. With the patient's permission, and usually after discussion with family, the employers should be contacted with a return to work strategy. This is likely to include an initial period off work; how long for will depend on clinical common sense, which will be guided by how long symptoms have been present. A firm medical recommendation that the patient requires a prolonged period off work may be needed; if patients are apprehensive about tight deadlines for returning to work, this is

likely to aggravate symptoms. Symptoms that have been present for months are not likely to improve in a few days or weeks, so a medical certificate of 3 months is a starting point, perhaps with guidance to the employers that depending on progress this may need to be extended. It is usually better to overestimate the time that will be needed, so that the employer and the patient are pleased should the latter be fit to start before the target date, rather than disappointed that the target date has passed and the patient has failed to return. On the other hand, it is important not to make blanket recommendations that all patients, including those with mild symptoms, have long periods of convalescence; for some this will cause frustration and may consequently aggravate symptoms, quite apart from the financial problems that may result, or the possibility that the job is jeopardised as a result.

Mood disorder and PTSD

Mood and anxiety disorders call for careful evaluation especially when long continued after injury, with readiness to explore the detailed factors operating in the individual case. The situation of the patient, including his family setting, must be comprehensively reviewed; where litigation is in progress liaison with the lawyers representing the case can be helpful. Antidepressant medication and the minor tranquillisers are valuable aids, but for many patients the mainstay of treatment lies in psychotherapy and in attention to the social problems that exist. Psychotherapy may need to consist of little more than ongoing support, reassurance and the ventilation of anxieties. More sophisticated psychotherapeutic interventions will need to take account of any cognitive impairment (Borgaro *et al.* 2003). Some patients may benefit from relaxation therapy, and this is often used alongside a formal anger management programme for patients with marked irritability and episodic loss of temper. If litigation is present, its speedy resolution is in general to be desired, certainly in cases where brain damage does not play an identifiable part.

PTSD is likely to require trauma-focused cognitive-behaviour therapy, shown to be effective in patients with PTSD without a brain injury. The cognitive-behaviour therapy may need to be adjusted and set within the context of a neurorehabilitation programme for those with significant cognitive impairment (Williams *et al.* 2003). It may be possible to prevent the development of PTSD by targeting those with an acute stress reaction and offering them early cognitive-behaviour therapy (Bryant *et al.* 2003); the proportion of patients with PTSD symptoms at 6 months was reduced from 58% to 17%.

Post-traumatic headache

Long-continued and disabling post-traumatic headache can pose a difficult therapeutic problem. Frequently a number of simple remedies will have been tried without success, and the headache will be found to be inextricably intertwined with a variety of other complaints. Evaluation and treatment

must give full attention to both organic and psychological factors. The range of organic causes that need to be considered has already been outlined in the Post-traumatic headache section (under Post-concussion syndrome) earlier in chapter. A recent review of treatment is not encouraging (Lew *et al.* 2006). The prognosis of post-traumatic headache that has lasted more than a few months is poor. One case series of 20 does suggest that cognitive-behaviour therapy may be useful (Gurr & Coetzer 2005).

Pharmacotherapy

Cognitive impairment

Two main classes of drugs have been used to improve cognition, including memory impairment, after head injury: drugs that enhance catecholamine transmission and drugs that enhance cholinergic transmission. In both cases it is useful to distinguish early effects to promote concentration and recover and reduce confusion, from late effects once cognitive impairments are static.

A systematic review of the value of the catecholamine agonists amantadine, amphetamine and methylphenidate for acute TBI concluded that there is insufficient evidence to support the routine use of these agents to promote recovery from TBI (Forsyth & Jayamoni 2003). Nevertheless, two small RCTs did find that both early amantadine (Meythaler *et al.* 2002) and methylphenidate (Plenger *et al.* 1996) may hasten recovery. More recently, a small RCT comparing methylphenidate and sertraline with placebo, 1 month post injury, tentatively concluded that methylphenidate seemed to be better at improving cognitive function (Lee *et al.* 2005). Whyte *et al.* (2004) studied the effects of methylphenidate, on average over 3 years after injury, on numerous measures of attention and memory. Over the 6 weeks of the study patients received alternate weeks of methylphenidate or placebo. Using a rigorous methodology they identified three measures of psychomotor speed, concentration and memory that were improved by methylphenidate. Bromocriptine may be able to improve executive function, including dual-task processing (McDowell *et al.* 1998).

Early case studies, including one small RCT (Cardenas *et al.* 1994) suggested that physostigmine, a short-acting cholinesterase inhibitor, might improve memory and reduce confusion after head injury (Goldberg *et al.* 1982; Eames & Sutton 1995). The newer generation of cholinesterase inhibitors, like donepezil, are much more convenient to administer. Numerous small case series have suggested that they seem safe, and may be effective for both early confusion (Walker *et al.* 2004) and late concentration and memory impairment (Morey *et al.* 2003; Tenovuo 2005). Two RCTs have assessed the effectiveness of donepezil and rivastigmine, respectively. Twenty patients with cognitive impairments, on average about 4 months after a head injury, entered a placebo-controlled cross-over trial comparing 10 weeks'

treatment with donepezil, mostly at 10 mg/day, with 10 weeks' placebo (Zhang *et al.* 2004). Measures of short-term memory and attention improved more quickly during donepezil treatment. However, in a study of rivastigmine (3–6 mg/day) and placebo over 12 weeks in 157 patients on average several years after a head injury with average duration of loss of consciousness of 3 weeks, no effects on a visual attention task or a memory task were found (Silver *et al.* 2006). A subgroup analysis hinted at improvements in those with more severe memory impairment on rivastigmine. Rivastigmine was shown to be safe and well tolerated. Therefore cholinesterase inhibitors may be useful, but should probably only be carefully tried in those with significant memory impairment. Practical aspects of treatment have been addressed in a useful review (Blount *et al.* 2002).

Behavioural problems

Although agitation and aggression are common problems after head injury, there is little good evidence to guide the clinician on which drug to use, and indeed whether any are in fact effective (Fleminger *et al.* 2003c). The literature is replete with case reports or small case series advocating the effectiveness of different drugs, but given that agitation tends to resolve spontaneously and that aggression is often very changeable, carefully controlled studies are needed. In this setting of uncertainty it is essential to ensure that medication is definitely necessary, to choose drugs with minimum potential for interactions and side effects, and to attend to the principles of drug treatment illustrated in Box 4.6.

Drug treatment for agitation is probably best avoided. Because agitation is often associated with the period of post-traumatic delirium, anything which increases confusion, and that includes almost all psychotropics, may increase agitation. In addition, any akathisia from antipsychotic medication will make agitation worse. There is therefore a good case for waiting, or for trying amantadine or methylphenidate.

For aggression the anticonvulsants carbamazepine and valproate have a strong track record, and given that they may have positive effects on mood are often a reasonable first

choice, particularly if epilepsy is present. The observation that valproate does not appear to jeopardise cognitive function is reassuring (Dikmen *et al.* 2000). On the other hand, if there is evidence of psychosis or fear or mania, then an antipsychotic should probably be tried. However, there are indications from animal studies that antipsychotics may hinder neuronal recovery, and the risk of tardive dyskinesia, and probably neuroleptic malignant syndrome, is increased in people with a brain injury. Given these concerns and the fact that there is no definitive research evidence of efficacy in this situation, for each patient the clinician needs to be confident that antipsychotic medication has helped and continues to be necessary, if it is to be prescribed long term. Because they are probably less likely to produce side effects, atypical antipsychotics are generally used, but their potential for sedation and weight gain may limit their value.

It is worth considering a trial of a benzodiazepine, being mindful of the potential for disinhibition of behaviour and for tolerance. Short-acting benzodiazepines are particularly likely to be addictive, and if given 'as required' may reinforce unwanted behaviour. Therefore it is probably best to use regular dosing with diazepam. Interestingly, the class of drugs that have been best studied are the beta-blockers. Several small RCTs suggest they may be effective. However, large doses were used in these studies, with many patients suffering side effects. An alternative is to try an antidepressant, for example trazodone, before considering a beta-blocker. One case series found treatment with sertraline to be associated with reduced irritability and aggression (Kant *et al.* 1998b).

Sexually disinhibited behaviour may respond to antipsychotic medication. Sometimes an anti-androgen is needed (Emory *et al.* 1995). However, it is important to remember that sexually disinhibited behaviour that occurs during the early stages of recovery is likely to resolve spontaneously as the period of post-traumatic confusion resolves. In this setting simple behavioural and environmental manipulations may be more appropriate.

Dopamine agonists probably have a specific role in the treatment of apathy (Marin & Wilkosz 2005). The only properly controlled study has looked at bromocriptine, which was found to improve motivation (Powell *et al.* 1996). In some patients the improvements in motivation seemed to persist even after bromocriptine was stopped, and this is in line with anecdotal observations in clinical practice. Bromocriptine had a selective effect on motivation, having no effect on depression.

Mood and anxiety disorders

The selective serotonin reuptake inhibitors (SSRIs) are probably the first choice for treating depression after head injury, not least because they tend to have few side effects and may help symptoms that commonly accompany depression, particularly anxiety and irritability (Alderfer *et al.* 2005).

Box 4.6 Principles of drug treatment

- No knee-jerk reactions
- Start low, go slow, add one at a time
- Beware cocktails and interactions
- Beware chasing your tail
- Beware 'as required' short-acting anxiolytics
- Trial of treatment: if it does not work, stop it – slowly

Choose drugs with less

- Potential for lowering seizure threshold
- Extrapyramidal and anticholinergic side effects
- Potential for drug interactions

However, there is little evidence on which to make recommendations. Two uncontrolled studies have used sertraline, one in patients with mild head injury (Fann *et al.* 2000) and the other in patients with acquired brain injury including head injury (Turner-Stokes *et al.* 2002), both finding that patients with major depression generally improved. Citalopram, like sertraline, has little propensity for drug interactions and is therefore a reasonable alternative. Drugs that interact with other drugs commonly used after head injury need to be managed carefully.

A 40-year-old man suffered two post-traumatic epileptic seizures in the first year after a severe head injury, but had not had any further seizures since starting carbamazepine 3 years ago. He had been on a combination of fluoxetine and carbamazepine for 2 years and depression-free for over 18 months. Within 1 week of stopping fluoxetine he had a seizure. Carbamazepine levels were found to be subtherapeutic. Because of deteriorating symptoms of depression, he was started back on the fluoxetine. Repeat carbamazepine levels, with no change in dose, were now in the therapeutic range. He had no further epilepsy.

However, depression in those who have suffered a head injury may be more difficult to treat than depression in the absence of brain injury (Dinan & Mobayed 1992). Therefore other classes of antidepressants may need to be considered if depression fails to respond to an SSRI. One uncontrolled case series suggests that moclobemide may be an alternative (Newburn *et al.* 1999). Trazodone, which has the advantage of being relatively sedative but with few anticholinergic side effects, is sometimes used, particularly if depression is accompanied by anxiety, insomnia or aggression. Electroconvulsive therapy is not contraindicated when other measures have failed (Kant *et al.* 1999), and can occasionally be dramatically effective in cases of severe depression or prolonged stupor following head injury (Silverman 1964).

Pathological laughing or crying, or emotional lability, sometimes responds dramatically to an SSRI (Sloan *et al.* 1992). One study found that citalopram seemed to be as good as paroxetine, but possibly had fewer side effects (Muller *et al.* 1999).

The management of patients with anxiety disorders, including obsessive-compulsive disorder and PTSD, following head injury must be guided by the principles of treatment used in patients without brain injury. For the post-concussion syndrome, if depression or anxiety is prominent then it is probably worth trying an SSRI.

Post-traumatic headache

There have been few thorough evaluations of what might help post-traumatic headache and the good results observed

in uncontrolled studies of valproate, propranolol and/or amitriptyline, and sumatriptan, are not always observed in clinical practice (Lew *et al.* 2006). Non-addictive analgesics have a place. Ergotamine preparations may be tried when episodic headache is suspected to have a vascular basis (McBeath & Nanda 1994). Antidepressants can sometimes produce results, but it is worth remembering that they themselves may cause headache.

Physical treatments often tried include local heat, and local anaesthetic injections to tender sites and to the upper cervical spine. These have a useful place (Hecht 2004), but when overemployed carry the danger of focusing attention exclusively on one aspect of the problem alone.

Mania, psychosis and confabulation

Psychoses, including mania, which develop after head injury generally require the same psychiatric management as the equivalent illnesses occurring in other settings. Of the mood stabilisers, the anticonvulsant valproate is likely to be the first option when treating mania, partly because of reports that lithium may exacerbate confusion and ataxia and reduce seizure threshold in patients with brain injury (Silvey *et al.* 2005).

Some patients will require an antipsychotic, in which case it is probably best to choose an atypical antipsychotic, taking into account the cautions described above. There are no systematic evaluations of antipsychotic use in patients who are psychotic after head injury. There have been case reports suggesting that risperidone is effective (Silvey *et al.* 2005), but depending on the circumstances olanzapine, quetiapine and aripiprazole are reasonable alternatives. It is perhaps worth considering clozapine in patients who have failed to respond to other antipsychotics and whose behaviour remains very difficult to manage (Michals *et al.* 1993). Because the occasional patient will suffer epilepsy as a side effect, some clinicians routinely add valproate when using clozapine in somebody with a head injury.

Clinical experience suggests that confabulations may be less likely to respond to antipsychotic medication than delusions. Cholinesterase inhibitors might be considered an alternative to an antipsychotic. Given that confabulations are often short-lived, there is often an argument for not offering drug treatment.

Children

A small RCT found that ADHD symptoms in children with head injury improved with methylphenidate treatment (Mahalick *et al.* 1998), although other studies have been less encouraging (Williams *et al.* 1998). Amantadine may improve behaviour and executive function (Beers *et al.* 2005).

Sleep

Insomnia at night is often associated with excessive sleep during the day. Therefore strategies to improve sleep at night

as well as maintain wakefulness during the day are likely to be required. For nocturnal insomnia, good sleep hygiene measures need to be put in place. Treatment with hypnotics is generally guided by the same principles as for insomnia in those without a head injury. Cautious use of benzodiazepine hypnotics is required and the non-benzodiazepine hypnotics like zopiclone are probably a better starting point. Sedative antidepressants should be considered, particularly trazodone. One small RCT comparing melatonin and low-dose amitriptyline (25 mg) with placebo in patients with chronic insomnia after head injury found small beneficial effects (Kemp *et al.* 2004). There was a tendency for melatonin to improve daytime alertness and amitriptyline to improve night-time sleep. For severe daytime sleepiness modafinil seems safe and may be appropriate (Teitelman 2001).

Post-traumatic epilepsy

This important complication needs to be managed along the same lines as epilepsy due to other causes. There may be a place, in carefully selected cases, for operative removal of an epileptogenic scar. Prophylactic medication for post-traumatic seizures occurring after the first week following closed head injury probably does not work (Schierhout & Roberts 1998). Patients who have been started on anticonvulsants but who have not suffered seizures after the first week generally need to be weaned off the medication by 6 months, unless the anticonvulsant is being used as a mood stabiliser or analgesic. Exceptions would include patients who had required neurosurgery, or with an open head injury or depressed skull fracture or epilepsy antedating the head injury.

Sexuality, social adaptation and effects on the family

Disturbances in sexual functioning and sexual relationships are widespread after head injury. Reduced levels of sexual drive, increased levels of erectile problems, ejaculatory and orgasmic difficulties and diminished frequency of intercourse have been reported at rates ranging from 30% to 60% in both civilian and veteran populations (Walker & Jablon 1959; Kreuter *et al.* 1998; Ponsford *et al.* 2003). For established couples, at least half report substantial dysfunction in their sexual relationship (O'Carroll *et al.* 1991). Sexual problems are not related to the gender of the patient but are associated with depression (Hibbard *et al.* 2000). This may be partly explained by the observation that SSRIs are often associated with side effects including decreased libido, erectile difficulties, delayed ejaculation and anorgasmia (Dolberg *et al.* 2002).

Many drugs impair sexual function and therefore the first stage of management is a thorough review of medication. If the patient is taking an SSRI, an antidepressant of another class with less propensity for causing sexual dysfunction should be considered. Sildenafil has proved effective in treating organic and psychogenic erectile disorders among head-injured patients, although significant care is required in

assessing the potential consequences of successful treatment on existing marital relationships. Existing sex therapy techniques for the treatment of ejaculatory disorders, modified to compensate for the motor sensory and cognitive sequelae of head injuries, have also been a useful approach (Simpson *et al.* 2003). National head injury consumer associations have developed information resources about the impact of head injury on sexual function. Finally, because many sexual problems are a reflection of broader relationship problems, they may need to be treated alongside marital therapy.

Sexually disinhibited behaviour is not uncommon after very severe head injuries during the period of recovery from post-traumatic delirium. In the majority of such cases the problem resolves spontaneously quite quickly. However, in a survey of outpatients admitted to a regional brain injury rehabilitation service, frotteurism, exhibitionism and coercive sexual behaviours were identified among 7% of a series of 445 patients (Simpson *et al.* 1999). Only 2 of 29 patients had a premorbid history of sexual offences.

Behavioural approaches employing techniques such as time out, dating skill training, self-monitoring of sexual urges, and scheduled staff feedback have been shown to be effective in treating mild to moderate levels of disinhibited behaviour (Zencius *et al.* 1990). In more severe cases of hypersexuality, often resulting in criminal sexual assaults, medroxyprogesterone acetate was found to be an effective management approach in one case series (Emory *et al.* 1995). The authors highlighted the importance of patient compliance with the medication, the necessity of providing cognitive-behaviour counselling as an adjunct to the pharmacotherapy, and the difficulties in preventing recidivism over the long term in cases where the patient had a comorbid substance abuse disorder.

Consideration of the sequelae of head injury is incomplete without mention of the broad effects on the quality of the patient's life and that of his family. It is abundantly clear that leisure and social activities are often profoundly disrupted, sometimes in the long term, quite apart from the consequences in terms of employment and finance. Family relationships can come under considerable strain. In all these respects the mental aftermaths, and particularly changes in personality, can prove more disruptive than the purely physical disabilities.

It was apparent in Thomsen's (1974) follow-up of severely head-injured patients that loss of social contact featured prominently among their problems. Most had lost touch with previous friends, and possibilities for making new acquaintances were few. Intellectual deficits, but even more so changes in personality, created the major problems in daily living. A prospective follow-up by Oddy and Humphrey (1980) reinforced these findings: leisure activities were still impaired 2 years after injury in half of their patients, this rarely being due to physical problems alone. Weddell *et al.* (1980) demonstrated marked changes in the social

milieu of young adults followed 2 years later, in terms of changes in work, leisure activities, contact with friends and family life. Working capacity was affected by neurophysical status, memory difficulties and personality problems; it was the last, however, which contributed most to loss of friendships and to dependence on the family.

Families make an extremely important contribution to the ongoing recovery of people with head injury. Most patients are discharged to the family home after acute hospitalisation or rehabilitation, where close relatives continue to provide long-term support. The impact of a relative sustaining a head injury on the broader family system has been extensively documented. Very strikingly, Rosenbaum and Najenson (1976) compared the wives of 10 patients suffering from severe head injury with those of paraplegic controls who had sustained no loss of cognitive function. At 1 year follow-up, the wives of the head-injured patients were significantly more depressed, had experienced greater changes in their lives and had suffered greater social restriction.

In family members, high rates of distress and disruption, ranging from 25% to 52%, have been reported for a range of indicators including depression and anxiety (Livingston *et al.* 1985) and subjective burden (Brooks, D.N. *et al.* 1987). In addition, there may be changes in family functioning such as reduced levels of communication, affective involvement general functioning, and role change (Anderson *et al.* 2002). Florian *et al.* (1989) highlighted a number of the particular challenges that arise for families in respect to head injuries. Lack of comprehension of the patient's behaviour and its origins can lead to unhelpful responses on the part of those around. Anger may arise from a suspicion that the patient is not making proper effort, or guilt that disappointing progress reflects the carer's own inadequacy. This circle of anger and guilt can lead to emotional distancing. Denial by parents or spouses of the severity of the impact of the injury may persist for many years, along with unrealistic expectations of progress; and with eventual disappointment this can turn to anger directed at those responsible for rehabilitation. The wives of patients often need to adjust to regressive child-like behaviour, to altered sexual behaviour, and to facing the burden of child care alone (Lezak 1978).

Investigations of the causes of distress in families and carers have focused on three broad domains.

1 The characteristics of the person with TBI: the most commonly identified predictors are behavioural and emotional sequelae of the injury, for example irritability, aggression, anger outbursts, depression, and self-centredness (Brooks & McKinlay 1983; Kreutzer *et al.* 1994), followed by cognitive impairments, such as memory problems or slowed information processing (McKinlay *et al.* 1981; Hall *et al.* 1994; Wallace *et al.* 1998). There is little association between physical impairments and distress of the family or carer.

2 The characteristics of the relatives: reliance on non-adaptive coping mechanisms (Sander *et al.* 1997), an at-risk psychosocial history (Hall *et al.* 1994), and the degree of

change between pre- and post-injury social roles (Leathem *et al.* 1996) correlate with the degree of distress experienced by the carers of the patient. A number of reports suggest that spouses experience greater distress than parents, but others have not found this to be the case.

3 The presence of social support for relatives has been identified as a mitigating factor (Ergh *et al.* 2002). The critical ingredient is that the relative should feel supported, rather than for example the size of their social network (Hall *et al.* 1994; Sander *et al.* 1997; Ergh *et al.* 2002). Other types of support, such as access to professional information and financial support, are also important (Leathem *et al.* 1996; Ergh *et al.* 2002).

Despite the extensive literature, there have been few studies evaluating the efficacy of family treatment. Long-term support often falls to self-help groups and charities, who provide counselling, support and social activities for patients and their families. For reasons such as these, the National Head Injuries Association (Headway) has been established as a voluntary charitable trust, with the aim of providing counselling, support and social activities for patients handicapped in the long term and for their families.

Cerebral Tumours

Nuria Mellado-Calvo and Simon Fleminger

Maudsley Hospital, London

Tumours involving the central nervous system (CNS) form a diverse group as regards their pathology and clinical course. In one study, the incidence rate for glial tumours was 6.7 per 100 000 population per year, accounting for approximately 51% of all CNS primary neoplasms (Bondy *et al.* 2005). However, brain metastases, predominantly originating in the lung and breast, are commoner than primary cerebral tumours by a ratio of 10 : 1 (Culine *et al.* 1998). Over two-thirds (70%) of all tumours are supratentorial and their distribution by lobe and age of onset are influenced to some extent by histology (Price *et al.* 2005) (Tables 5.1 and 5.2). For example, medulloblastomas are most common in the posterior fossa and in children, whereas gliomas predominate in the middle-aged population and meningiomas and metastatic disease are more frequent in the elderly (Price *et al.* 2005) (Table 5.3).

There is little good evidence for the role of electromagnetic fields, cell phones producing non-ionising radiation, diet, alcohol, tobacco, exposure to industrial chemicals, or medications as aetiological factors in the pathogenesis of brain tumours. Ionising radiation (Grayson 1996), electromagnetic radiation (Hardell *et al.* 2000) and viruses may play a role in some. For example, SV40 and JC viruses have been found in paraffin-embedded cerebral tissue of children with medulloblastoma (Khalili 2001). There could be a negative association between varicella-zoster herpesvirus and the development of glioma in adults; those with gliomas have been found to have higher levels of anti-varicella-zoster IgG (Wrensch *et al.* 2005).

Genetic susceptibility

The association of hereditary syndromes with cerebral malignancies is well known. Turcot's syndrome is characterised by the presence of adenomatous polyposis of the large intestine and high-grade astrocytomas and medulloblastomas. In the neurofibromatoses, increased rates of glioma are

seen in neurofibromatosis (NF)-1, and multiple meningiomas and bilateral vestibular schwannomas in NF-2. The nevoid basal cell carcinoma syndrome has been linked with medulloblastoma and Gardner's syndrome with glioma (Bondy *et al.* 2005). In Li-Fraumeni syndrome, individuals present with sarcomas and multiple cancers affecting the breast and brain (Li *et al.* 1998).

The possible contribution of alterations in the genetic material to tumour formation has been reviewed by Hill *et al.* (1999). Mutations in tumour-suppressor genes may be responsible. Examples include (i) p53, located on chromosome 17p, and found in 40% of astrocytic tumours of all grades; (ii) CDKN2 (cyclin-dependent kinase, involved in the cell cycle) mutation on chromosome 9p in high-grade astrocytomas; and (iii) deletions of chromosome 10, which occur frequently in astrocytic tumours. There is evidence for the presence of tumour-suppressor genes on chromosome 10 (Ichimura *et al.* 1998).

In some cases there is activation of an oncogene leading to increased cell proliferation, for example epithelial growth factor receptor (EGFR) is amplified in malignant astrocytomas. As noted above patients with NF-2 are at risk of meningiomas and schwannomas. The *NF2* gene is located on chromosome 22q12. Its protein product, merlin, is a cytoskeletal protein. It is truncated when mutated, resulting in structural abnormalities that presumably lend themselves to tumour formation. Deletion of loci on chromosome 22q occurs in approximately 30% of sporadic meningiomas.

Other mechanisms that may be involved in the development of oncogenicity include abnormalities in signal transduction pathways. For instance, 55% of meningiomas express the *ROS1* tyrosine kinase oncogene. Platelet-derived growth factor receptor (PDGFR) overexpression has been observed in gliomas. Intracellular second messengers such as Ras (a monomeric GTPase named after the *ras* gene first identified in viruses that cause rat sarcomas) have been

implicated; increased activity is found in high-grade gliomas and correlates with the rapid proliferation of these tumours. Increased *in vitro* activity of protein kinase C (PKC), another intracellular messenger, is associated with high growth rate in gliomas (Martin & Hussaini 2005). There may be important genetic influences on treatment of cerebral tumours. In low-grade gliomas, the allelic loss of chromosomes 1p and 19q renders them chemosensitive (Rees 2002).

General characteristics of neuropsychiatric symptoms

Patients with brain tumours typically present with headaches, papilloedema, seizures, focal neurological deficits, or non-specific cognitive or personality changes. The clinical constellation of symptoms varies depending on the location, histology and tumoral rate of growth (Wen *et al.* 2005). Occasionally, the earliest manifestations may consist of mental symptoms alone. When mental disturbance is the most prominent feature, the patient may come first to the attention of the psychiatrist. It is, of course, comparatively rare for the psychiatrist to find a cerebral tumour in a patient with mental disorder. Parry's (1968) finding of 1 per 200 patients admitted to a psychiatric unit is probably higher than average. However, the converse is extremely common and many patients with cerebral tumours show pronounced mental symptoms at some time in their course. The frequency has been reported variously as 10% to virtually 100% of cases, depending on the care with which psychological symptoms are sought. Two of the larger series of tumour patients studied personally by the authors, and with psychological symptoms in mind, were those of Keschner *et al.* (1938) and Hécaen and Ajuriaguerra (1956). Keschner *et al.* reported mental symptoms in 78% of 530 cases, Hécaen and Ajuriaguerra in 52% of 439 cases (Table 5.4).

From the clinical point of view, mental symptoms are generally of little use as a guide to the location or nature of the tumour. Neurological signs are greatly superior in this regard, and neuroimaging has diminished the importance

Table 5.4 Prevalence of mental symptoms with cerebral tumours.

Location of tumour	Study 1 (Keschner <i>et al.</i> 1938)*			Study 2 (Hécaen & Ajuriaguerra 1956)†

* Excluding paroxysmal disturbances.

† Including paroxysmal disturbances.

even of those mental symptoms which might have been of value. Tumour material has also proved disappointing for the study of the cerebral basis of mental phenomena. It is often hard to disentangle the effects of the lesion itself from remote pressure effects, circulatory disturbances or the generalised effects of raised intracranial pressure. Nevertheless, the psychological effects of cerebral tumours show many features of interest, and can occasionally be of crucial clinical importance, affecting the quality of life of the patient. Although fatigue, emotional and existential issues are common in all cancer patients, the presence of depressive symptoms was the single most important predictor of quality of life in a cohort of 73 brain tumour patients (Pelletier *et al.* 2002).

Changes may be seen in any aspect of psychological function, and may be localised to one aspect or quite widespread. Alterations in level of consciousness, cognition, the affective state and other functions that may be described as 'change of personality' are not infrequent. Complex psychological symptoms such as hallucinations and delusions may also appear, and the picture can be complicated by paroxysmal disorders consequent on an epileptogenic focus. Occasionally, frank psychotic illnesses are seen or more frequently stress-related disturbances occasioned by the constitution of the individual. In the exceptional case the tumour will present with psychiatric symptoms, but more usually the psychiatric symptoms accompany a tumour that is already known to be present. Minski's (1933) report of psychiatric symptomatology among patients from the Maudsley Hospital is typical: 25 of 58 patients with cerebral tumour showed 'functional' mental illness, and in almost half of these physical signs were absent. Fourteen patients displayed severe depression, seven excitements, and one each showed schizophrenia, an anxiety state, an obsessional disorder and hysteria.

In very general terms it may be said that slow-growing tumours tend to produce changes of personality, and allow

premorbid tendencies to manifest themselves; more fast-growing tumours lead to cognitive defects, whereas the most rapid lead to acute organic reactions with obvious impairment of consciousness.

Cognitive changes

Disturbance of cognitive function is the most commonly noted psychological change. In minor degree it shows as diminished capacity to attend and concentrate, faulty memory and easy fatigability. These rather subtle changes may be the first manifestation of the lesion, and sometimes provide the sole indication of disease for long periods of time. The cognitive changes may encompass changes in memory, attention, problem-solving, psychomotor speed and visuospatial functioning, among other deficits (Garofalo & Baum 2001).

More severe cognitive impairment may present in the form of dementia, with slowed and concrete thinking, impoverished associations, defective judgement and obvious difficulty with memory. Perseveration is sometimes marked. Speech may be slowed and incoherent, even in the absence of dysphasia and even with tumours of the non-dominant hemisphere. Such changes can be steadily progressive, but more characteristically tend to fluctuate in severity from one occasion to another.

Focal cognitive changes are commoner than generalised dementia as befits the focal nature of the lesion. Or a focal emphasis may be detected even when global deterioration is present. A circumscribed amnesic syndrome may appear while other functions remain well preserved, with markedly defective memory for recent events, disorientation and even confabulation. All varieties of dysphasia can be seen, also apraxia, visuospatial defects and topographical disorder, and serve as a guide to location. Certain cognitive disturbances characteristic of tumours are considered in the following text.

Disturbance in the level of consciousness/delirium will add to the cognitive changes, again tending to fluctuate with periods of lucidity. Later, drowsiness and somnolence appear, and as the lesion extends the level of consciousness declines progressively, ending, if untreated, in coma.

Cognitive function is an important marker of prognosis. In patients with glioma those with poor cognitive function have a worse prognosis (Meyers *et al.* 2000a; Klein *et al.* 2003). This is probably partly explained by the observation that tumour regrowth (local or diffuse) or leptomeningeal metastases may induce cognitive deficits (Taphoorn & Klein 2004). Importantly, cognitive deterioration may indicate tumour progression before there is evidence of recurrence on computed tomography (CT) or magnetic resonance imaging (MRI), as evidenced by Meyers and colleagues after evaluating 56 patients with recurrent brain tumours in which cognitive deterioration preceded radiographic changes by 6 weeks (Meyers *et al.* 2000a; Meyers & Hess 2003).

The effects on cognition of the treatment of cerebral tumours may have important repercussions for quality of life in both children and adults. This is particularly relevant given the improvements in survival time that are now being seen. Whereas the cognitive dysfunction following surgery appears to be less significant in adults (Tucha *et al.* 2001), provided it does not damage eloquent tissue, a moderate level of neuropsychological morbidity has been reported in children (Carpentieri *et al.* 2003). In addition radiation-induced neurotoxicity in the brain is a well-known phenomenon and a cause for concern (see also section on Management of the tumour; Radiotherapy). Its complications may be acute and reversible or delayed and permanent (New 2001). Neurological complications have been described with the use of chemotherapy and biological therapies (Hildebrand 2006), ranging from headache to cognitive slowing and even encephalopathy.

Lower non-verbal memory scores have been found in patients with low-grade glioma treated with chemotherapy and radiotherapy compared with those receiving no treatment (40 patients, 24 receiving no treatment) (Correa *et al.* 2007). In 28 patients with primary CNS lymphoma, those receiving more aggressive forms of treatment showed deficits in the memory and attention executive domains, especially those who received radiotherapy as opposed to those treated with methotrexate-based chemotherapy (Correa *et al.* 2004).

Therefore it has been suggested that a comprehensive assessment of cognitive functions, activities of daily living and quality of life can provide insights into the degree of impairment due to the tumour and neurotoxicity following its treatment (Weitzner & Meyers 1997).

Affective and anxiety disorders

Anxiety, sleep difficulties and depressive illness are common in patients with brain tumours (Stark *et al.* 2002). Depressive

symptoms may have an overall incidence of 20–25%. Organic factors, such as tumour location, may play a small part in the aetiology. Other significant stressors include the disability caused by the tumour, and being diagnosed with a life-threatening illness. The majority of those at more advanced stages of the disease or with severe disability and/or pain are likely to have significant depressive symptoms. The Karnofski score, a measure of performance status in cancer patients (with lower scores indicating greater disability), is inversely correlated with the severity of depressive symptoms (Bukberg *et al.* 1984).

Affective changes rarely occur in isolation, but frequently accompany other mental manifestations. With intellectual impairment there tends to be emotional dullness, apathy and asponaneity; alternatively, euphoria may stand in striking contrast to what would be expected in view of the patient's physical defects and disabilities. However, depression and anxiety are also common with cerebral tumours, sometimes as understandable adjustment reactions and sometimes pathological in degree. Irritability can be a prominent feature particularly early on (Henry 1932), or there may be emotional lability with marked and evanescent swings of mood. Sustained elation is rarely seen. Suicidal tendencies occur in perhaps 10% of cases.

Pringle *et al.* (1999), in their prospective study of 109 patients, reported that 16% were depressed preoperatively and 6% postoperatively. Of the cohort of 40 patients with gliomas or meningiomas studied by Anderson *et al.* (1999), 15% reported depression following surgical treatment. The same rate of depression has been reported by physician ratings of depression following surgical treatment for glioma; this increased to 22% over the 6-month postoperative period (Litofsky *et al.* 2004). In this study a much higher rate (93%) of patients reported symptoms consistent with depression. One interpretation is that physicians miss depression in these patients. On the other hand, it is easy to overestimate rates of depression if the diagnostic instrument used fails to distinguish between demoralisation and major depression (Pace & Pompili 2005). Using *Diagnostic and Statistical Manual of Mental Disorders* (DSM)-IV criteria, Wellisch *et al.* (2002) found that 28% of their sample of 89 ambulatory patients fulfilled the diagnosis of major depressive disorder, key predictors being frontal location, family history and combined sadness and lack of motivation. As many as 50% of patients with brain tumours face existential issues akin to patients with cancer (Pelletier *et al.* 2002). In this study of 73 patients with primary brain tumours, depression, fatigue, emotional distress and existential issues correlated with one another, but it was depression that best predicted quality of life. Tumour laterality may have an effect on patients' perception of their quality of life. In their study of 101 patients, Salo *et al.* (2002) found that patients with tumours located on the right or in the anterior region reported poorer quality of life than those with a tumour on the left side or posteriorly.

Rates of anxiety disorders may be increased in cerebral tumours and location may be of significance. In their cohort of 101 patients, Mainio and colleagues found that, preoperatively, patients with a tumour in the right hemisphere had statistically significant mean anxiety scores compared with those who had a tumour in the left hemisphere. These scores declined after 3 months and 1 year after surgery on the patients with a right-sided tumour (Mainio *et al.* 2003). Mainio *et al.* (2005) studied 59 patients with primary brain tumours and assessed their obsessionality preoperatively and postoperatively. Whereas there was no significant difference preoperatively, obsessionality scores were higher in the patients with a tumour in the left anterior region of the brain, measured at 3 months postoperatively and predominantly in women ($P = 0.036$), as compared with other regions of the brain. Peterson *et al.* (1996) identified three children, from more than 800 presenting to their speciality obsessive-compulsive disorder (OCD)/Tourette clinic over 10 years, in whom symptom progression of OCD or tics seemed to be related to progression of a primary cerebral tumour. One had an optic chiasm glioma that involved hypothalamus, thalamus, ventral striatum and nucleus accumbens; one had a left parietal glioma involving corpus callosum, cingulate gyrus and caudate nuclei; and one had a midbrain glioma with hydrocephalus and involvement of periaqueductal grey matter and the thalamus. The authors suggested that involvement of the limbic system was common to all three cases.

Psychotic symptoms

Hallucinations may occur in any modality, commonly as part of an epileptic disturbance but also without evidence of paroxysmal activity. The nature of the hallucinations will depend on the location of the tumour. Occipital tumours are associated with simple visual hallucinations; temporal lobe tumours with more complex formed visual and auditory hallucinations, also gustatory and olfactory hallucinations; and parietal lobe tumours with localised tactile and kinaesthetic hallucinations. However, the distinctions are not absolute. Circumscribed frontal lobe tumours may sometimes produce visual, auditory or even gustatory hallucinations, presumably through effects on the neighbouring temporal lobe. Medial frontal lesions can also discharge directly to the temporal lobe and produce hallucinations and other phenomena by this means. Peduncular hallucinosis caused by brainstem compression has been described in a variety of posterior fossa tumours (Roser *et al.* 2005; Mocellin *et al.* 2006). These are usually self-limited and resolve spontaneously. Visual perseveration (palinopsia) and auditory perseveration (palinacousis) in the context of ictal activity have been reported in a patient with a left temporoparietal astrocytoma (Auzou *et al.* 1997).

Any form of delusional illness may accompany cerebral tumour, either early or late in its evolution. Depressive,

schizophrenic, paranoid and hypomanic illnesses have all been reported, usually but not always in association with evidence of organic brain dysfunction. When they occur, delusions may have a characteristic organic colouring, being poorly elaborated, shallow or fleeting.

Factors governing symptom formation

In terms of the nature of the tumour, by and large the main factors related to symptom formation are its rate of growth, the presence or absence of raised intracranial pressure, and the size of the tumour. It has not been possible to identify precise relations between tumour location or histological type and the likelihood of mental sequelae. In addition, the role of individual differences in symptom formation is often overlooked, partly because it may be difficult to study. However, it should be remembered that in patients with a special predisposition to mental disorder, the tumour may act as little more than a precipitating factor in the psychiatric disturbance that develops.

Raised intracranial pressure and cerebral oedema

A good deal of the neuropsychiatric symptomatology is a consequence of raised intracranial pressure. Resolution of confusion, drowsiness, apathy and even coma have followed lowering of intracranial pressure, either by decompression or dexamethasone. The pathophysiology of these effects may lie largely with disturbance of the brainstem reticular formation and its rostral projection to the cortex, or with direct compression of brain tissue, impeded circulation and impaired flow of cerebrospinal fluid (CSF). After long-continued elevation of pressure there may be extensive parenchymal damage resulting from such factors, and the mental impairments will then remain even after the pressure is lowered. Focal effects in the region of the tumour may also be aggravated by increased pressure, as seen for example when dysphasic symptoms recede as the pressure is lowered.

Even when intracranial pressure is not raised, there are likely to be other important factors at work leading to the appearance of mental symptoms. Of these, localised cerebral oedema in the neighbourhood of the tumour is clearly of special importance. Psychiatric sequelae of meningiomas were found to correlate with the extent of peritumoral oedema rather than the size of the tumour itself (Lampl *et al.* 1995). The pathophysiological mechanism implicated in the appearance of psychiatric symptoms in the context of cerebral oedema could be attributed to the disruption of intracerebral pathways rather than the single pressure effect *per se*.

Nature of the tumour

It seems likely that the rapidity of growth of a tumour is one of the most important factors determining the incidence and

Fig. 5.1 Glioblastoma multiforme. Axial post-contrast CT shows a large rim-enhancing tumour involving and causing marked expansion of the splenium of the corpus callosum. The tumour extends into both adjacent cerebral hemispheres. This appearance may also be described as a butterfly glioma.

severity of mental symptoms, and tumour volume and rapidity of growth appear to be better predictors of impaired cognitive function than histology alone (Kayl & Meyers 2003). Keschner *et al.* (1938) found that tumours which produced no mental symptoms whatsoever were mainly of the slow-growing type. The observation that symptoms were more frequent with malignant tumours than benign (Busch 1940) may be explained by rate of tumour growth. This might also be one of the reasons why gliomas have repeatedly been found to produce a higher incidence of mental disturbance than meningiomas. In Hécaen and Ajuriaguerra's (1956) series, for example, mental disturbances were noted in 61% of gliomas compared with 43% of meningiomas. Furthermore, within the group of gliomas, rapidity of growth appears to be important; Busch (1940) found much higher rates of symptoms in patients with glioblastomas (70–80%) (Fig. 5.1) than in those with lower-grade astrocytomas (25–35%).

Poorer quality of life has been reported in patients with the most malignant (WHO grades III and IV) gliomas compared with those with less aggressive histology (Salo *et al.* 2002). Metastatic tumours with several deposits scattered throughout the brain have proven to be associated with a larger prevalence of mental disturbance than any variety of primary intracerebral tumour (Keschner *et al.* 1938).

Location of the tumour

The importance of tumour location in relation to mental symptoms has been much debated. Many observations concerning special regional effects can be offset by negative findings. Bleuler (1951), reviewing 600 unselected tumours from the Zurich neurosurgical clinic, suggested that the psychopathological picture was in fact very uniform; 83% of his patients showed mental symptoms, but there were no significant differences according to the site of the tumour. Only two mental syndromes could be reliably differentiated: clouding of consciousness in the acute stage, and a 'chronic amnesic syndrome' in the chronic stage. The latter embraced more than memory defects alone, also including widespread cognitive disturbances, emotional instability and impairment of personality. However, it seems likely that local effects may be seen, for example focal cognitive deficits with parietal tumours and focal amnesic syndromes with diencephalic tumours. Hallucinations also clearly derive from focal lesions of the brain.

When considering more than such relatively elementary symptoms, it becomes harder to demonstrate the role of focal cerebral disorder in the pictures that result. Thus disturbances of affect and personality cannot be tied convincingly to tumours in specific parts of the brain, and psychotic illness appears to be largely determined by other factors. Frontal and temporal lobe tumours show a somewhat higher frequency of mental disturbances than do tumours of the parietal or occipital lobes (Keschner *et al.* 1938; Hécaen & Ajuriaguerra 1956).

Frontal lobe tumours

Frontal lobe tumours are notorious for their ability to present under guises that may lead to the mistaken diagnosis of a primary dementing illness. This is partly due to the paucity of striking neurological signs accompanying frontal lesions, and partly to the frequency with which mental disturbances appear from an early stage. When considering the effects of frontal lobe tumours it is useful to remember the clinical syndromes that may be observed following orbitofrontal lesions compared with lesions affecting dorsolateral prefrontal lobe or anterior cingulate (Cummings 1993).

Impairment of consciousness and intellectual deterioration were found more frequently with frontal lobe tumours than with tumours of any other location in Hécaen and Ajuriaguerra's (1956) series. Sachs (1950), in a large series of patients with meningiomas, found eight who presented with dementia before any symptoms indicative of tumour had appeared, and in six the tumours were frontal in location. Sometimes dramatically successful results can follow the removal of such a tumour.

A woman of 64 was admitted to hospital in a deteriorated state and unable to give an account of herself. Her husband stated that the illness began 2 years previously when she became excessively preoccupied with the ills of her pet dog. For 3 months there had been episodes of trembling all over, but not associated with any loss of consciousness. She had gradually become forgetful and muddled and had lost all initiative. For 3 weeks she had been confined to bed and was too confused to dress herself. She was doubly incontinent. There had been no headache, fits or vomiting.

On examination she showed a profound dementia with disorientation in time and place. She lay inert in bed but was not difficult to rouse. There was no dysphasia or apraxia, but she could not cooperate with detailed tests of intellectual function. The only neurological signs were a persistent tremor of the outstretched hands and an equivocal left plantar response. The sense of smell was intact. Electroencephalography (EEG) showed evidence of a lesion in the left frontotemporal region, and skull radiography showed erosion of the posterior clinoid processes. At operation a left frontal parasagittal meningioma was removed.

Two months postoperatively her mental state was judged to be entirely normal and she said she felt better than for several years. She recalled little of her preoperative condition except that she had been distressed over her incontinence (Sachs 1950).

A woman developed grand mal epileptic fits at the age of 40, and at 53 was admitted to a psychiatric hospital because she had become apathetic, inert, incontinent and bedridden. She was aggressive when approached and deteriorated in habits. Skull radiography was interpreted as showing hyperostosis frontalis interna. After 12 years in hospital she remained severely demented, was somnolent and showed little response to questions. She sat with the tongue protruded to the right, and making purposeless repetitive movements of the right arm and leg. She was anosmic, could only just distinguish between light and dark, and showed a left-sided facial weakness. There was no obvious weakness of the limbs but she could neither stand nor walk.

Investigations revealed a massive bifrontal meningioma, probably attached to the crista galli. After its removal she made a remarkable improvement, regained some degree of spontaneity, speech and sight and was able to get about. She recognised and talked with relatives for the first time in 12 years. She had a dense amnesia for the 15–20 years before the operation and misjudged events and ages accordingly (Hunter *et al.* 1968).

According to Lampl *et al.* (1995), tumours of the left frontal lobe appear to be associated with greater cognitive disturbance than tumours of the right. In their study of 50 patients with meningioma, those with tumours in the base of the skull were free of psychiatric symptoms, whereas 44% of the patients with convexity meningiomas presented with psychiatric morbidity consisting of major depression in nine (four with psychotic features), atypical depression in four, and unspecified psychosis in three. Smith's (1966) careful analysis of psychometric tests showed greater losses in both verbal and performance abilities in left compared with right frontal tumours, the difference still persisting when aphasic patients were excluded. Bilateral involvement, as with tumours originating in the midline, produce more disturbance than when a single lobe is implicated alone (Strauss & Keschner 1935).

Generalised dementia is the most frequent picture, but disturbance of memory can occasionally be seen in relative isolation. The disturbances of affect most characteristic of frontal lobe tumours appear to be irritability, depression, euphoria and apathy. Occasionally, anxiety and obsessional symptoms may coexist (John *et al.* 1997). Irritability is repeatedly stressed and may occur as a presenting symptom. Some of the patients reported by Direkze *et al.* (1971) had initially been admitted to psychiatric units on account of depression, which then proved to be unresponsive to electroconvulsive therapy. Euphoria and apathy generally occur along with intellectual enfeeblement, or in conjunction with other organically determined changes of personality. Chee *et al.* (1985) have charted improvement in six patients with frontal meningiomas who presented with dementia, sometimes with recovery postoperatively to normal intellectual function as confirmed by psychometry.

Frontal lobe tumours may present with changes of disposition and behaviour, even in the absence of intellectual deficits or neurological signs. This appears to be characteristic of slow-growing meningiomas. In Strauss and Keschner's (1935) series of frontal tumours, for example, change of personality was one of the earliest manifestations in almost one-quarter of patients. Irresponsibility, childishness and lack of reserve are changes stressed most frequently.

The wife of a 60-year-old man was surprised to find that her husband had forgotten to buy her a birthday present one year, and that he seemed quite unconcerned about this oversight. This was quite out of character for him. Around the same time he lost his job as a bus driver, because of concerns from his managers that he was behaving unreasonably when asked to take on work. Over the next few weeks and months he became increasingly apathetic and thought-

less. He would sit around at home doing nothing. He became unreliable, socially disinhibited and no longer took proper care of household belongings. At no time was he obviously depressed nor did he complain of headaches nor suffer any seizures. Over the course of the next few months he developed urinary incontinence.

MRI brain scan revealed an enhancing lesion in the midline consistent with a meningioma (Fig. 5.2). The tumour was removed and found to be a grade 2 meningioma. Postoperatively he was left with executive impairment, verbal and physical aggression, and a confabulatory state. These symptoms gradually improved but he was left with persisting cognitive impairment.

Of 25 patients reported by Direkze *et al.* (1971), 11 presented with subtle personality alterations.

A 53-year-old clergyman began outlining rather smutty jokes, a greengrocer was charged on five occasions for speeding, all within 3 weeks, and a pharmacist became forgetful, easily provoked and asked his wife to play cowboys and Indians with him. All proved to have astrocytomas.

Disinhibition sometimes leads to striking social lapses or minor misdemeanours as the first obvious sign of change:

A man of 58 presented with a 12-month history of extravagance, boastfulness, excessive drinking, marital discord, unrealistic planning and several changes of job. He had held a responsible job in a senior position. He showed a happy confident manner and believed he was rich, but was self-neglectful and lacking in insight. The plantar reflexes were upgoing and there was papilloedema on the left with reduced visual acuity. A left olfactory groove meningioma was discovered (Avery 1971).

On the other hand, frontal tumours may present with mania. Starkstein *et al.* (1988) found that of six patients with tumours who developed mania either before or after surgical removal, all but one were frontal or temporal in location; there also appeared to be a special relationship with right hemisphere involvement.

Severe urgency, frequency and incontinence are often presented early in the course of a frontal tumour, and can occur in the absence of dementia, indifference or lack of social concern (Andrew & Nathan 1964; Maurice-Williams 1974). The ability to inhibit the micturition reflex appears to be impaired, likewise ability to stop the flow once it has begun. A similar disorder of defecation may develop, though less often and less severely. Contrary to common teaching, the patients are usually upset and embarrassed by their incontinence at this stage, although later on it may emerge in the context of general indifference and self-neglect.

Fig. 5.2 There is a T2 isointense, homogeneously enhancing, extra-axial tumour arising from the falx and extending laterally on both sides to distort the frontal lobes. T2 hyperintensity reflecting vasogenic oedema is noted in the frontal white matter bilaterally. (a) Axial T2-weighted image; (b) Axial T1 post-gadolinium image.

Corpus callosum tumours

Tumours originating within the corpus callosum are notorious for the severity of the mental disturbances that follow. A large series was reported by Schlesinger (1950), who found mental changes in 92% when the rostrum was involved, in 57% with mid-callosal tumours and in 89% with tumours of the splenium. In a small consecutive series, Selecki (1964) confirmed the special frequency of mental symptoms with anterior and posterior tumours compared with those arising from the middle portion. Anterior tumours tended to lead to rapid mental deterioration before the appearance of neurological sign, headache or other evidence of raised intracranial pressure. Rudge and Warrington (1991) have drawn attention to the special tendency for tumours of the splenium to present with marked deficits of memory and visual perception, sometimes while other aspects of intellectual function are relatively well preserved.

The usual picture is of a rapidly progressive impairment of intellectual functions, beginning with marked memory difficulties. Sometimes there is striking blocking of thought and action which may resemble that seen with catatonic schizophrenia. Alpers (1936) thought that the clinical picture was often sufficiently characteristic for the diagnosis to be made directly.

A man of 64 had a 4-week history of behaving strangely at work, seeming oblivious of questions and unable to focus his attention. At home, he would sit in the same place for hours at a time, once wound a clock for 3 hours on end, and once lathered his face for 2 hours. On examination there was bilateral spasticity but no papilloedema. He sat staring ahead oblivious of his surroundings, or with his eyes closed picking aimlessly at the bed clothes. Sometimes he lay for long periods tapping his head with his hand. It was hard to make contact with him, and most questions met with no response. He was disoriented, but at times seemed to recognise people. Perseveration was extremely marked. He proved to have a glioblastoma practically confined to the genu of the corpus callosum (Alpers 1936).

Personality changes may also be an early feature, similar in all respects to those seen with frontal lobe tumours. Florid psychotic symptoms have also been reported (Murthy *et al.* 1997). In his comprehensive review, Elliott (1969) suggests that the combination of delusions and stupor can come to resemble schizophrenia closely. A large part of the mental disturbance is probably due to the tendency for tumours of the corpus callosum to involve adjacent structures. Almost all involve the third ventricle and diencephalon at some stage, which presumably accounts for the somnolence, akinesis and stupor which ultimately appear.

Fig. 5.3 Gliomatosis cerebri. Axial FLAIR (fluid-attenuated inversion recovery) image shows subtle and diffuse hyperintensity throughout much of the white matter of the left cerebral hemisphere. Apart from slight effacement of the cerebral sulci, there is little distortion of the brain architecture. Signal abnormality is also shown within the right thalamus.

Gliomatosis cerebri (Fig. 5.3) is a rare neoplasm in which individual neoplastic cells diffusely permeate the brain, usually starting with extensive infiltration of the white matter including the corpus callosum, with later involvement of basal ganglia, other cerebral nuclei and cerebral cortex (Filley *et al.* 2003). It has been suggested that the dementia syndrome seen in gliomatosis cerebri resembles that found in other diseases with selective involvement of cerebral white matter, for example multiple sclerosis or HIV dementia. Early on there are subtle cognitive and emotional changes, which are then followed by deficits in sustained attention, memory retrieval, visuospatial skills and frontal lobe function but with sparing of language for example. This picture is said to be characteristic of white matter dementia (Filley 1998).

Temporal lobe tumours

Temporal lobe tumours (Fig. 5.4) produce perhaps the highest frequency of mental disturbances (Table 5.5). In part this may be ascribed to the paroxysmal phenomena occasioned by temporal lobe epilepsy. Apart from features particular to temporal lobe epilepsy, there does not seem to be any form of mental disturbance specific enough to be of localising value. Non-dominant temporal lobe tumours can be clinically silent until they are very large, whereas tumours on the dominant side tend to produce the greater cognitive

disturbances in both verbal and non-verbal functions (Bingley 1958).

Often the symptoms of temporal lobe tumours are akin to those of frontal lobe tumours, for example slowing and asynchronicity of speech and movement are seen in both. Memory disturbances may likewise feature prominently, including occasional cases that present with a florid Korsakoff syndrome or pure amnesia (Umemura *et al.* 1997). Impairment of semantic memory with preservation of autobiographical memory has been reported in a meningioma

Fig. 5.4 Temporal high-grade astrocytoma. Axial T2 image shows an extensive area of T2 hyperintensity in the right temporal lobe.

producing bilateral damage of the anterior part of the middle region of the temporal lobe (Yasuda *et al.* 1997).

Affective disturbances are common. Paroxysms of anxiety or anger have been described, and occasional cases have presented with mania or hypomania. Exacerbation of mania, previously stabilised pharmacologically, has been described in a patient with a right temporal lobe astrocytoma (Sokolski & Denson 2003).

In their review, Gupta and Kumar (2004) reported personality changes with left frontal and left temporal meningiomas. However, there does not appear to be a form of personality change specific for temporal lobe tumours. A change towards facetiousness, foolish joking and childish behaviour may be indistinguishable from that seen in frontal lesions, and has been reported to be just as common. Strobos (1953) observed marked personality alterations in 7 of 62 patients with temporal lobe tumours, including psychopathic and paranoid trends, hypochondriasis and extreme irritability.

Occasionally, patients with temporal lobe tumours develop psychotic illnesses resembling schizophrenia, which may be the initial manifestation. Such cases are rare, but were drawn together in a review of the literature by Davison and Bagley (1969). The location of the tumour in 77 cases of 'schizophrenia' from 42 published reports was compared with two large unselected series of tumours. A significantly higher proportion of temporal lobe and pituitary tumours were present in the 'schizophrenic' group. There was insufficient information to indicate whether such patients had been genetically predisposed to schizophrenia, or whether temporal lobe pathology might have played a more direct aetiological role.

Some isolated clinical examples rather strongly suggest that the temporal lobe pathology may itself be responsible: see following case vignettes.

Table 5.5 Prevalence of forms of mental disturbance with cerebral tumours.

Location of tumour	Study 1 (Keschner <i>et al.</i> 1938)*					Study 2 (Hécaen & Ajuriaguerra 1956)†		
	No. of cases	Disturbance of consciousness (%)	Change of intellect (%)	Disturbance of memory and orientation (%)	Disturbance of affect (%)	No. of cases	Intellectual disturbance (%)	Affective and personality disturbance (%)

* Excluding paroxysmal disturbances.

† Including paroxysmal disturbances.

A 53-year-old woman with a previous sociable and outgoing personality was admitted to hospital after attacking her husband with a knife. She felt persecuted by her family, believing that they were attempting to harm her and that her son was turned into a dog. She complained of severe headache and thoraco-epigastric pain. On examination, her speech was incoherent and she displayed bizarre facial mannerisms and sudden unpredictable behaviour. She became stuporose and died. A glioblastoma in the right temporal lobe was found (Haberland 1965).

A 51-year-old woman without a psychiatric background presented with a 15-year history of attacks of visual disturbance in the right visual field and 1-year history of grand mal epilepsy. A left temporal astrocytoma was partially removed and she made an excellent recovery. Two years later, she became depressed for several weeks after her husband suffered a stroke. Her depressive symptoms improved, but she gradually developed a number of odd ideas and occasional hallucinations in the right half visual field. She was admitted to hospital several months later. At that time, she obviously displayed first-rank schizophrenic symptoms and persecutory delusions. On examination, there was evidence of thought disorder, with preservation of personality with warm affect. She had relative insight into the abnormal nature of her beliefs and experiences. A return of her dysphasia was observed as well as an upper quadrantic field defect and slight dropping of the outstretched right arm. The EEG showed an increase in slow activity in the left frontotemporal region. She was commenced on chlorpromazine and her psychotic symptoms and neurological deficits improved, regaining full recovery within 2 months. The EEG improved to its baseline state. Residual dysphasic symptoms manifested, especially when tired with occasional grand mal fits, minor epileptic attacks and a persistent deficit of recent memory. Unfortunately, 1 year later, she died after gradual neurological deterioration. The post-mortem revealed a recurrence of the tumour in the left frontotemporal region.

In addition to patients who present with symptoms of schizophrenia, the complex hallucinations of temporal lobe tumours may lead to diagnostic confusion. Visual and auditory hallucinations can be either simple or complex, the latter being especially liable to lead to a mistaken diagnosis of psychotic illness. Visual hallucinations occurring within a hemianopic field of vision are particularly characteristic of temporal lobe disturbance. Olfactory and gustatory hallucinations may arise from the uncinate region. It has been suggested that the patient accepts such hallucinatory

Fig. 5.5 Parietal oligodendroglioma. Axial FLAIR image shows a hyperintense lesion in the left parietal lobe involving cortex and subjacent white matter. Histology revealed a grade II oligodendroglioma.

experiences as real at the time of their occurrence, but thereafter rapidly regains insight into their abnormal nature.

Epilepsy occurs in approximately 50% of patients with temporal lobe tumours, which is commoner than with tumours in other locations (Paillas & Tamalet, 1950; Strobos 1953). In addition to hallucinatory experiences, the epileptic auras may contain a variety of abnormal subjective experiences that lead to diagnostic difficulty, including unreality, *déjà vu*, dreamy states, forced thoughts, overwhelming fears and other sudden emotional changes.

Parietal tumours

Tumours of the parietal lobe (Fig. 5.5) are less likely than frontal or temporal lobe tumours to produce psychological changes, including personality change, and more likely to lead to early neurological signs in motor and sensory systems. Erroneous diagnosis of primary psychiatric disorder is therefore uncommon. Nevertheless, depression has been noted with considerable frequency (Hécaen & Ajuriaguerra 1956). Hallucinatory experiences consist of tactile or kinaesthetic hallucinations confined to the opposite half of the body, also 'tactile perseveration' as when the patient continues to perceive a contact long after the stimulus has been removed.

The principal psychiatric interest attached to parietal lobe tumours lies in the complex and fascinating cognitive disturbances that may occur (see Chapter 2). At first sight these may very occasionally be mistaken for hysteria; for example unilateral inattention or neglect with anosognosia,

associated with non-dominant tumours, might look like a conversion disorder. Critchley (1964) stressed other similarities between hysteria and parietal disease: difficulties with communication may make it hard to secure the patient's attention and cooperation, and performance may show marked inconsistencies such that the patient succeeds in a task which a moment before had appeared to be beyond him. The epileptic manifestations that accompany parietal lobe tumours, and which may antedate the appearance of neurological signs, sometimes consist of transient disturbances of body image. These again may be sufficiently bizarre to suggest a non-organic psychiatric disorder. Examples reported by Hécaen and Ajuriaguerra (1956) included the spasmodic feeling of someone standing close by, absence or displacement of a part of the body, transformation of a limb into a mechanical object, and the phantom appearance of a third limb. On the other hand, when the cognitive disturbances of parietal lobe are accompanied by marked indifference or social withdrawal the presentation may raise the possibility of dementia.

Occipital tumours

Patients with occipital lesions tend to be spared psychiatric sequelae, although they are at increased risk of raised intracranial pressure causing a disturbance of consciousness. Amnesic difficulties and dementia can occasionally be striking. Visual agnostic defects can be valuable in localising features.

Diencephalic tumours

Tumours originating in the deep midline structures of the diencephalon (i.e. thalamus, hypothalamus and other structures in the neighbourhood of the third ventricle) may produce striking disturbances with important localising significance. The most important of these are memory impairment, often with confabulation, hypersomnia and akinetic mutism. Particularly in children, hyperphagia with obesity may be the presenting symptom.

Marked amnesic difficulties, often with confabulation, are typical of tumours located in the neighbourhood of the third ventricle (Sproffkin & Sciarra 1952; Delay *et al.* 1964). Of the 180 patients with cerebral tumours systematically studied by Williams and Pennybacker (1954), 26 had impairment of memory as the outstanding cognitive defect. More than half of these 26 patients had tumours involving the region of the third ventricle. The four patients with a classic amnesic-confabulatory syndrome all had localised lesions directly involving the floor or walls of the third ventricle.

Burkle and Lipowski (1978) describe a patient in whom memory deficits were accompanied by such prominent psychiatric disorder that the organic nature of her troubles was at first overlooked. The lesion, a colloid cyst (Fig. 5.6, though not in the patient described) of the third ventricle, was eventually removed with excellent results.

Fig. 5.6 Colloid cyst. CT shows a hyperdense rounded lesion in the left foramen of Monro causing a localised obstructive hydrocephalus, mainly of the left lateral ventricle.

A woman of 24 complained of increasing depression, sleepiness, loss of interest and memory lapses. Her depression had been coming on gradually over several months. On examination she was disoriented for the day of the week, showed poor recall of objects, but had no neurological abnormalities. She was apathetic, spoke slowly and stared impassively. A diagnosis was made of severe depression. Further examination confirmed marked impairment of judgement and recent memory, and she was considered to be affectively flat rather than depressed. The possibility was raised of hysteria or an organic brain syndrome. Skull radiography surprisingly showed evidence of raised intracranial pressure, and a CT scan showed dilated lateral ventricles and a spherical mass in the third ventricle. A colloid cyst was removed and she ultimately made a full recovery (Burkle & Lipowski 1978).

Somnolence and hypersomnia are frequent with diencephalic tumours and consequently have some localising value, for example in a patient with disturbances of memory or intellect. It is necessary to distinguish true hypersomnia from the impairment of consciousness that results from raised intracranial pressure. The hypersomnia due to diencephalic lesions is essentially an excess of normal sleep, and when roused the patient awakens normally and fully; patients with torpor due to raised intracranial pressure may

similarly be roused, but usually display muddled awareness and obvious intellectual impairment. Very rarely, attacks virtually undistinguishable from idiopathic epilepsy or cataplexy occur, with uncontrollable drowsiness and weakness of the limbs. These may be provoked by laughter or other sudden emotional reactions.

Frequently, but not invariably, the sleep disturbances are accompanied by other evidence of hypothalamic disorder, such as amenorrhoea, diabetes insipidus or voracious appetite. Disturbances of thermoregulation may cause pyrexia and lead to a mistaken diagnosis of an infective process. Tumours affecting the hypothalamus or third ventricular region in childhood, such as pinealomas or craniopharyngiomas, can lead to delayed sexual development or occasionally to precocious puberty. These varied disturbances may occur in the absence of somnolence.

Akinetic mutism, first described by Cairns *et al.* (1941) in a patient with an epidermoid cyst of the third ventricle (see case study below), is another syndrome seen with lesions of the posterior diencephalon or upper midbrain (see Chapter 1, under Diencephalon and brainstem, and Causes of stupor). When caused by a cystic tumour that can be aspirated, the akinetic mutism can be potentially reversible. A dense amnesic gap is then left for the duration of the episode. It may occasionally need to be distinguished from depressive or catatonic stupor.

The patient sleeps more than normally, but he is easily roused. In the fully developed state he makes no sound and lies inert, except that his eyes regard the observer steadily, or follow the movement of objects, and they may be diverted by sound. Despite his steady gaze, which seems to give promise of speech, the patient is quite mute or answers only in whispered monosyllables. Oft-repeated commands may be carried out in a feeble, slow and incomplete manner, but usually there are no movements of a voluntary character, no restless movements, struggling or evidence of negativism. Emotional movement also is almost in abeyance. A painful stimulus produces reflex withdrawal of the limb and, if the stimulus is sustained, slow feeble voluntary movements of the limbs may occur in an attempt to remove the source of stimulation, but usually without tears, noise or other manifestations of pain or displeasure.

Personality change may be the most striking mental symptom. In some there will be features of frontal lobe disturbance: carelessness, fatuous serenity, disinhibition and lack of concern for those around. Indifference to the gravity of the condition may be striking, with affirmation of well-being and denial of illness. Complex disturbances of personality have also been reported.

A patient of 39 was found at post-mortem to have a teratoma of the third ventricle which had destroyed the hypothalamus, but without evidence of hydrocephalus or cortical damage. For a year before the signs of the tumour developed he had become irritable, hypersensitive, aggressive, unreasonable and stubborn, in contrast to his previous personality. He had shown periods of great excitement, and frequently flew into a rage over trivial matters. Meanwhile, his business judgement had become impaired and he had become careless of responsibilities. Ultimately he exhibited severe loss of memory (Alpers 1937).

Thalamic tumors

Patients with thalamic tumors have been reported to show early and severe dementia, which may run a rapid course (Lagares *et al.* 2004). Smyth and Stern (1938) reported six such cases. In two, severe dementia coexisted with little evidence of raised intracranial pressure or ventricular dilatation, and at post-mortem examination the tumour had not extended widely into the surrounding white matter. The focal lesion may therefore be significant in itself in causing intellectual disturbance. Abnormalities of pupillary reflexes were common in Smyth and Stern's cases. However, neurological signs may be absent, as in the case of a 65-year-old woman with bilateral thalamic glioma who presented with personality changes and progressive cognitive deterioration (Kouyialis *et al.* 2004), or only appear late.

Hamartomas

Hamartomas (Fig. 5.7) are malformations consisting of hyperplastic neuronal tissue in an ectopic area. Reeves and Plum (1969) reported a patient whose dementia was accompanied by outbursts of rage and marked hyperphagia; at post-mortem, a circumscribed hamartoma was found in the hypothalamus.

It is now recognised that hypothalamic hamartomas may present with aggression, precocious puberty and gelastic seizures (Weissenberger *et al.* 2001). Laughing attacks may be seen as early as the first year of life with other epileptic attacks, sometimes of multiple forms, being seen often before age 10. By this time behavioural problems and cognitive impairment are often evident (Berkovic *et al.* 1988). Cognitive impairments are seen in the majority of patients and it has been suggested that this is at least partly due to epilepsy (Deonna & Ziegler 2000). This may be explained to some extent by the adverse effects of antiepileptic medication on cognition. Frattali *et al.* (2001) also found greater cognitive impairment in those with more severe seizures, and proposed that the deficits in long-term retrieval and processing speed are associated with conduction pathways involving the amygdala and hippocampal formation.

Fig. 5.7 Hypothalamic hamartoma. Sagittal T1 post-gadolinium image shows a large pedunculated non-enhancing mass arising from the hypothalamus and extending inferiorly into the interpeduncular cistern.

Fig. 5.8 Craniopharyngioma. CT shows a part solid, part calcified cystic mass in the suprasellar region.

Ali *et al* (2006) studied psychiatric morbidity in 10 patients with hypothalamic hamartomas and found high rates of mood and anxiety disorders. Eight patients had a past or present diagnosis of at least one anxiety disorder; of these,

social anxiety disorder was the most common. Six patients had a current or past history of an affective disorder. They proposed that involvement of limbic structures with their connections to the hypothalamic–pituitary–adrenal axis might account for some of the symptoms.

Craniopharyngiomas

Craniopharyngiomas (Fig. 5.8), when coming to light in middle or old age, may present with failing intellect and memory in the absence of obvious neurological signs (Russell & Pennybacker 1961). This excess of memory defects remains even after the effects of raised intracranial pressure are controlled for. One of Williams and Pennybacker's patients illustrates the distinction that can at times be made between the general mental changes of raised intracranial pressure and the specific memory changes related to the focal lesion.

A young man of 22 was found to have a craniopharyngioma involving the floor of the third ventricle. It had interrupted circulation of the CSF and caused a marked rise in intracranial pressure, producing some local brainstem signs, severe confusion, drowsiness and intermittent coma. Ventricular tapping relieved these symptoms and he became alert and cooperative. However, a marked memory deficit for recent events then emerged, with elaborate and detailed confabulation. Part of the tumour was cystic and was directly tapped, thereby reducing local pressure on the hypothalamus. Following this he became fully orientated and his confabulation ceased. As the cyst again filled up, the amnesic–confabulatory syndrome reappeared. As the CSF circulation was again interrupted and general tension rose, so drowsiness and mental confusion supervened. These sequences were repeated on several occasions.

The clue in such diencephalic dementias may lie in somnolence or other symptoms of hypothalamic disturbance, but these are not obvious in every case. These tumours are strategically situated so as to compress the optic chiasma, and therefore often produce visual symptoms and signs that the patient is often unaware of. Spence *et al.* (1995) describe a patient with a craniopharyngioma who presented with a major depression. Here the clues to the presence of the tumour lay in hypersomnia and hyperphagia, in contrast to the insomnia and anorexia that had characterised previous bouts of depression. Another feature, always deserving of note, was the failure to respond to antidepressant medication. Hyperphagia may be particularly problematic in children with craniopharyngioma. One explanation is that the hypothalamus becomes insensitive to leptin, a hormone that binds to the satiety centre of the hypothalamus and which thus controls food intake (Roth *et al.* 1998).

Temper outbursts have been described. A relationship between hypothalamic lesions and intermittent explosive disorder was found in two case reports of craniopharyngioma with involvement of the hypothalamo-hypophyseal region (Tonkonogy & Geller 1992). However, one carefully designed study failed to demonstrate any excess neuropsychiatric morbidity in 18 patients after surgery for craniopharyngioma compared with control subjects who had been operated on for pituitary tumours (Bellhouse *et al.* 2003). This lack of effect may be explained by the fact that the authors were only able to interview those who were less symptomatic; only about half of the patients who were still alive after surgery, on average about 5–10 years before, were available or agreed to be interviewed.

Pituitary tumours

Tumours arising from the pituitary gland may present with raised intracranial pressure, pituitary dysfunction or visual failure. Mental changes may be found at an early stage and well before these other features are marked.

With some forms of pituitary tumours the psychiatric picture may be partly attributable to the endocrine disturbances that result, for example when Cushing's disease develops with basophil tumours or acromegaly with acidophil tumours. The common prolactin-secreting adenoma may be accompanied by marked depression, which resolves when prolactin levels are corrected. It is therefore hard to apportion the blame between the effects of hormonal changes and the effects of the CNS lesion, but there is general agreement that much of the psychiatric disturbance is due directly to extensions of the tumour beyond the sella turcica. Upward extension occurs in the direction of the third ventricle and will cause the mental symptoms typical of diencephalic tumours. Forward extension may occur between the frontal lobes, or laterally into the temporal lobe, all of which will contribute to the picture that ensues. They are also well situated to cause obstruction to the circulation of the CSF, with additional effects on the mental state due to raised intracranial pressure.

A range of disturbances are seen: hypothalamic disturbances with somnolence, polyuria and obesity, circumscribed amnesic states, deterioration of personality, and epilepsy including the uncinate fits of temporal lobe epilepsy. Dullness, apathy and passivity appear to be particularly characteristic, with mental slowing out of proportion to changes in intracranial pressure. Lack of concern may be striking, even in the face of progressive blindness. Emotional instability is also stressed, with liability to episodes of irritability and sudden rage.

Korali *et al.* (2003) studied 93 patients with pituitary adenoma presenting to an endocrine clinic. Half had a non-functioning adenoma. Using the Composite International Diagnostic Interview and a symptom checklist (SCL 90R), they found no good evidence of an increased risk of psycho-

pathology compared with a population sample of 481 subjects. There was a suggestion of an increased risk of somatoform disorders, and in men an increased risk of depression. However, another study investigated 33 women with growth hormone deficiency due to pituitary disease (Bulow *et al.* 2002). The majority had been operated on for pituitary tumours and had received radiotherapy. Approximately half of them had visual dysfunction. Compared with population-based controls, higher rates of mental symptoms including somatisation, anxiety and depression were found. There was evidence of intellectual impairment as well; the cases had lower scores in four of seven neuropsychological tests.

Lower quality of life has been reported even in patients with non-functioning pituitary adenomas. One case-control study of 99 patients in long-term remission following surgical treatment of a non-functioning pituitary adenoma found that patients reported higher levels of fatigue, changes in emotional reaction and limitation of role compared with the controls (Dekkers *et al.* 2006).

Posterior fossa tumours

Under this heading are included tumours of the cerebellum, cerebellopontine angle and brainstem (Fig. 5.9). As already seen, tumours originating below the tentorium cerebelli have a considerably lower incidence of mental symptoms than those originating above, despite the fact that raised

Fig. 5.9 Pilocytic astrocytoma in a 10-year-old male. Axial T1 post-gadolinium image shows a part cystic, part solid enhancing mass in the right cerebellar hemisphere resulting in complete effacement of the fourth ventricle. There is an associated obstructive hydrocephalus (not shown).

intracranial pressure is much commoner and tends to occur earlier.

Cognitive disturbances are often closely tied to evidence of raised intracranial pressure. The intellectual impairment is usually global, and amnesic defects or other focal cognitive deficits rarely appear in isolation. The impairments usually develop insidiously, and parallel the development of internal hydrocephalus caused by obstruction to flow of CSF. For example, Aarsen *et al.* (2004) found a significant relationship between the severity of preoperative hydrocephalus and impairment of visuospatial skills in children after surgical treatment for cerebellar pilocytic (low-grade) astrocytoma. Very slow-growing subtentorial tumours sometimes result in profound ventricular dilatation before they present for attention, and by then dementia may be severe.

It is easy to understand how hydrocephalus secondary to a posterior fossa tumour might cause significant cognitive and behavioural sequelae. Similarly, such sequelae might occur when the tumour, or its treatment, involves areas in the brainstem serving cortical arousal. However, over recent years there has also been interest in the possibility that damage confined to the cerebellum might have non-motor sequelae and produce a *cerebellar cognitive affective syndrome*. This was first described by Schmahmann and Sherman (1998) in adults with a variety of cerebellar lesions, including strokes, hypoplasia and tumours. It was posited that cognitive sequelae observed in these patients included executive, verbal, visuospatial, and attentional and memory deficits and that these were often accompanied by disinhibited or inappropriate behaviour and flattening of affect. These findings are consistent with those of Wilson and Rupp (1946) over half a century before; 5 of 21 patients had initially been admitted to psychiatric units with symptoms of memory disturbance, confusion, retardation of thinking and emotional instability; in these cases evidence of raised intracranial pressure was sometimes absent at the time of presentation.

Evidence of cognitive and affective sequelae following discrete cerebellar damage has also emerged from the study of children with posterior fossa tumours. Levisohn *et al.* (2000) studied 19 children who had only received surgery for their cerebellar tumour, and in whom the damage was therefore probably confined to the cerebellum. They were tested on average 5 months after surgery. A range of cognitive impairments was seen and there was a tendency for extensive lesions involving the cerebellar vermis to be associated with abnormal regulation of affect, for example irritability, disinhibition and lability of affect. These findings have been corroborated in a study that compared cognitive outcomes in young adults who had been treated, on average about 15 years previously when they were children, for either low-grade cerebellar astrocytomas (12 cases) or posterior fossa medulloblastoma (11 cases) (Ronning *et al.* 2005). Because the astrocytoma group only received surgical treatment, the authors suggested that in this group the damage was limited

to the cerebellum, whereas the medulloblastoma group, who received surgery, chemotherapy and radiotherapy, had more widespread damage. The astrocytoma group fared better than the medulloblastoma group, but both had impaired scores on measures of motor speed, attention and executive function.

It has been suggested that not only are lesions of the cerebellar vermis particularly likely to be associated with changes in affect, but that right cerebellar lesions are more likely to be associated with verbal deficits and left-sided lesions with non-verbal deficits, presumably reflecting the crossed cerebellar connections (Gottwald *et al.* 2004). However in a study of 103 children with cerebellar astrocytomas, tested on average 108 days after surgery, no evidence of an effect of lesion location was found, although the study did confirm the presence of cognitive impairment across the group as a whole (Beebe *et al.* 2005).

In children recovering after surgery for posterior fossa tumours, a syndrome of mutism and other behavioural problems in the early postoperative days is sometimes seen. This is sometimes referred to as cerebellar mutism, or the syndrome of cerebellar mutism and subsequent dysarthria, and sometimes as the *posterior fossa syndrome*. There is thus uncertainty as to the extent this acute syndrome is related specifically to cerebellar effects, or to problems elsewhere within the posterior fossa. It was labelled the posterior fossa syndrome in a study of 142 children following resection of posterior fossa tumours (Pollack 1997); 12 children, of whom seven had a medulloblastoma, developed transient mutism and in each case the tumour involved the cerebellar vermis. In general mutism developed 1–4 days postoperatively and typically was associated with neurobehavioural abnormalities including emotional lability, reduced initiation of movement and poor oral intake. The changes were generally transient, resolving after weeks or months. Because this neurobehavioural syndrome was generally associated with bilateral pontine oedema, the authors suggested that any of a number of sites within the posterior fossa might have been affected and therefore labelled it posterior fossa syndrome. Similarly, in a study of over 250 children with posterior fossa tumours who underwent surgical resection, 20 cases (8%) of posterior fossa syndrome were identified (Doxey *et al.* 1999). The most frequent postoperative findings included mutism, lasting on average about 10 weeks, as well as more permanent neurological sequelae such as ataxia and hemiparesis. In 16 of the 20 cases the tumour was a medulloblastoma. On the other hand, a similar constellation of symptoms, centred on acquired mutism lasting between 1 day and 5 months, was observed in 12 of 42 children following surgery to tumours localised to the cerebellum (Catsman-Berrevuets *et al.* 1999); it was labelled as the syndrome of cerebellar mutism and subsequent dysarthria. Again, children with medulloblastoma, often involving the cerebellar midline/vermis, were at greatest risk, as were those with tumours greater than 5 cm in

diameter. More recently, a study of patients seen in a psychiatric liaison service has highlighted changes in mood and behaviour (Turkel *et al.* 2004); 19 children mostly with midline lesions, 17 with tumours and two with arteriovenous malformations were found within days of posterior fossa surgery to be dysphoric, inattentive, to have psychomotor retardation or be withdrawn and apathetic, or be agitated and irritable; 10 were transiently mute and 14 required ventriculoperitoneal shunting for hydrocephalus. The changes were regarded as similar but more acute to those seen in the cerebellar cognitive affective syndrome.

The effects just described are found after the child has presented with neurological symptoms. However, occasionally, posterior fossa tumours appear to lead to early and pronounced changes of behaviour. In Hécaen and Ajuriaguerra's (1956) series there were four cases of cerebellar tumour in children that had produced anxiety, withdrawal, and deterioration in school work, hyperactivity and problems of control. Cairns (1950) reported three children with astrocytomas of the pons in whom the initial symptoms included irritability, fretfulness, cruelty and obstinacy. In two of these, symptoms were sufficiently pronounced to constitute a complete change of character, and in all three they antedated the appearance of headache or the development of physical signs.

Some mental sequelae can be understood as reactions to the neurological disability. For example, Bristow's (1991) two patients with tumours of the brainstem had reacted to dizziness, loss of balance and other minor symptoms by becoming depressed or anxious, and had initially been diagnosed as neurotic. However, in other cases mental symptoms can be traced to direct effects of the tumour on brainstem pathways or to raised intracranial pressure. Shepherd and Wadia (1956) reported six patients with acoustic neuromas in whom chronic hydrocephalus produced confusion, impaired memory, change of personality and lack of insight. In two the mental changes were the presenting feature. Woodcock (1967) found mental changes including personality deterioration, impairment of memory and intellect, confusion, depression, euphoria and neurotic traits in 7 of 30 cases and concluded that these were attributable to vascular disturbances consequent on brainstem distortion.

Psychotic symptoms have been reported in a surprising number of cases, chiefly depressive or paranoid psychoses occurring in clear consciousness (Dobrokhotova & Faller 1969; Scott 1970). Manic or mixed states have been described in three adults with acoustic neuroma (Kalayam *et al.* 1994). Visual hallucinations may occur with subtentorial tumours, presumably via pressure effects transmitted through the tentorium to the adjacent occipital cortex (see above).

Investigations

When there are grounds for seriously suspecting the existence of a tumour, neurological or neurosurgical help should

be obtained without delay. In the meantime preliminary investigations will need to include a full medical examination, including a neurological examination, and chest radiography to exclude metastatic disease. Neurological examination may need to be augmented by quantitative evaluation of visual fields using a combination of Goldman kinetic perimetry and Humphries static perimetry, particularly if there is suspicion of a tumour in the vicinity of the pituitary. Audiometry may be a useful screening test for the diagnosis of cerebellopontine angle tumours, for example 98% of patients with vestibular schwannoma have sensorineural hearing loss on pure tone audiometry.

Haematological, biochemical and immunological tests should form part of the basic diagnostic armamentarium. Endocrinological evaluation to assess the functioning of the hypothalamic-pituitary axis before and after treatment is important in the management of tumours in this region as well as in brain tumour patients treated with radiotherapy, as these patients frequently develop hormonal deficits.

An MRI brain scan (see below) will be the most important investigation, except in those in whom there are contraindications to MRI, in which case CT brain scanning will be required. Neither skull radiography nor EEG are particularly useful investigations. Although seizures are the presenting symptoms in about one-third of patients, in approximately 20% of cases a normal EEG is obtained, so the investigation cannot be relied upon to exclude the possibility of a tumour. Malignant tumours produce more EEG abnormalities than benign; in fact meningiomas may occasionally yield abnormal tracings only several years after the onset of clinical symptoms. Evoked potentials, such as brainstem auditory-evoked potentials and visual-evoked potentials, have a role in the diagnosis and monitoring of neurological function during surgical resection of tumours.

Ultrasonography may be the screening procedure of choice for infant and fetal brain tumours. Cytology may be useful in the diagnosis of pineal region tumours, often difficult to biopsy. It may be an asset in the postoperative staging of tumours as the presence of leptomeningeal involvement influences prognosis and treatment. Pineal germ-cell tumours secrete biological markers such as α -fetoprotein, the β -subunit of human chorionic gonadotrophin and placental alkaline phosphatase into the CSF. Their detection assists in the diagnosis and monitoring of the tumours (Wen *et al.* 2005). It should be emphasised that a lumbar puncture carries risks for patients with raised intracranial pressure and should be avoided in these circumstances (Wen *et al.* 2005).

Neuroimaging (see Chapter 2)

Structural neuroimaging using MRI is the mainstay of the investigation of suspected tumours; CT may be an adequate alternative. MRI and CT can be expected to give firm indications as to site, and the nature of the tumour may also be

disclosed. The capacity to distinguish tumours from infarction at an early stage is particularly useful, and in cases of doubt repetition after an interval of 2–3 weeks will usually clarify the issue. In addition to direct visualisation of the tumour mass, important information is obtained from brain displacements, surrounding oedema and changes in the overlying bone.

With CT, a meningioma is shown as an extra-axial lesion of immediate or slightly increased density, whereas gliomas and metastases may be either hypodense or hyperdense. Calcification, which is quite common in meningiomas, craniopharyngiomas and oligodendrogliomas, or bleeding within the tumour may be detected. If there is suspicion of a mass on CT, then post-contrast scans are required to characterise it further. Cystic or necrotic areas may also be clearly displayed.

MRI is the gold standard for the diagnosis of brain tumours. Its increased sensitivity, excellent tissue contrast and good resolution allow the detection of very small lesions. The images are not degraded by artefact from overlying bone, and the capacity to image in multiple planes can yield extra information about tumour size, shape and position. MRI frequently shows that the tumour and its associated brain response is more extensive than suspected on CT, and gadolinium enhancement helps delineate the tumour margins from surrounding oedema. The typical changes on T1 and T2 sequences, according to tumour type, are shown in Table 5.6 (Nabors 2005). Variants of standard MRI sequences, including perfusion and diffusion MRI, magnetic resonance spectroscopy or magnetic resonance angiography, and functional MRI, may occasionally be useful supplementary investigations. They may help define tumour characteristics, evaluate blood flow and measure volume, and thus improve management and assessment of prognosis (Nabors 2005). Nevertheless, MRI does have its limitations with respect to cerebral tumours (Box 5.1).

Positron emission tomography (PET) and single-photon emission computed tomography (SPECT) allow the detection of tumours as the result of their neurochemical and physiological responses, such as increased blood flow to the tumour, protein production or glucose consumption (Nabors 2005). They can be combined with other techniques to improve diagnostic accuracy and it has for example been suggested that these techniques allow radiation necrosis to be distinguished from tumour, which is often difficult with CT or MRI (Taphoorn & Bromberg 2005). Chao *et al.* (2001) studied 47 patients treated with stereotactic radiosurgery and followed them with MRI and ^{18}F -fluorodeoxyglucose (FDG)-PET to determine the ability of these investigations to distinguish radionecrosis from recurrent tumour. For brain metastases FDG-PET was able to diagnose recurrent tumour with a sensitivity of 65% and a specificity of 80%, using follow-up MRI or pathological conformation as the gold standard, whereas MRI coregistration with FDG-PET increased the sensitivity to 86% and a specificity at 80%.

Box 5.1 Limitations of MRI (Nabors 2005)

- Patient limitations (pacemakers, foreign metallic objects, claustrophobia)
- Lower sensitivity for calcified tumours
- Treatment (i.e. corticosteroids) may influence enhancement
- Enhancement does not always correlate with histological grade or definition of tumour borders
- Prior radiotherapy and surgery may influence T2 signal and extent of post-contrast enhancement
- Low specificity (i.e. infections and abscesses)

Computed tomography angiography is useful for excluding the presence of an aneurysm which may resemble a tumour in the sellar region. Catheter angiography may be required to evaluate vascular tumours such as meningiomas, with a view to preoperative embolisation.

Problems with misdiagnosis

Over the last 30 years more ready access to neuroimaging has dramatically reduced the likelihood that a cerebral tumour will be missed. Nevertheless, in the past, surveys of post-mortem material from psychiatric hospitals gave cause for concern. About 1 in 30 patients was found to have a cerebral tumour: Patton and Sheppard (1956) found 3.7% to have a cerebral tumour, Raskin (1956) 3.5% and Andersson (1970) 3%. In non-mental hospitals the rates are probably lower: Patton and Sheppard (1956) found cerebral tumours in 2.4% of those dying in a general hospital. Moreover, this difference was significantly greater for benign meningiomas, which constituted 33% of the tumours in mental hospitals but only 14% in non-mental hospitals.

Further evidence that benign meningiomas appear to be over-represented in psychiatric patients comes from a comparison of Raskin's (1956) series from the Boston State Psychiatric Hospital with two large series from neurological units as reported by Sumner (1969). Gupta and Kumar (2004) carried out a 5-year retrospective study of case records selecting patients whose psychiatric symptoms antedated the diagnosis of brain tumour. This study demonstrates the propensity for meningiomas to present with psychiatric symptoms; 80% of the 79 patients had presented with affective symptoms in the guise of anxiety or depression.

Dumas-Duport (1970) suggests that when tumour types are studied in a living psychiatric population the frequencies approach much more closely those of the general population; it is only when post-mortem psychiatric material is studied that the proportion of meningiomas rises and the proportion of gliomas falls so markedly. This is probably because post-mortem surveys deal mostly with chronically hospitalised patients, and meningiomas tend to produce chronic pictures of mental disorder and therefore tend to be missed. The predilection of meningiomas for the anterior

Table 5.6 Summary of imaging features of brain tumours. (Modified from Nabors 2005 with permission.)

Pilocytic astrocytoma (WHO grade I)

Cerebral, cerebellar, thalamic, ventricular location
Tumour nodules show intense enhancement
Hypointense to isointense on T1-weighted images
Hyperintense on T2-weighted images

Astrocytoma (WHO grade II)

Well-defined homogeneous masses
Calcification present in up to 50%, although not always evident
Hypointense on T1-weighted images
Hyperintense on T2-weighted images

Anaplastic astrocytoma (WHO grade III)

Heterogeneous images, less well-defined borders, greater mass effect, vasogenic oedema and enhancement
Heterogeneous signal intensity on non-contrast T1- and T2-weighted images

Glioblastoma multiforme (WHO grade IV)

Poorly defined with mass effect and vasogenic oedema. Haemorrhage is common
Heterogeneous signal intensity on both T1- and T2-weighted images
Signature: large region of high signal on T2-weighted images (oedema + microscopic tumour infiltration)
Good visualisation on T2 FLAIR

Oligodendroglioma

Calcification frequent
Heterogeneous in signal intensity
Predominantly isointense with grey matter on T1-weighted images and hyperintense on T2-weighted images

Medulloblastoma

Calcification frequent
Heterogeneous in signal intensity
Predominantly isointense with grey matter on T1-weighted images and hyperintense on T2-weighted images

Ependymoma

Posterior fossa in children, spinal cord in adults
Hypointense to isointense on T1-weighted images, hyperintense on T2-weighted images

Meningioma

Extra-axial
Hypointense to isointense on T1-weighted images, isointense on T2-weighted images
Homogeneous enhancement

Craniopharyngioma

Sellar to suprasellar location
Calcifications present on CT
Cystic components may contain cholesterol and may be hyperintense on T1-weighted images
Mixed signal on T2-weighted images
Solid portion shows enhancement with contrast

Primary central nervous system lymphoma

Immunocompetent: single lesion, peripheral location
Immunosuppressed: multiple lesions with deeper location (basal ganglia)
Hypointense to isointense on T1-weighted images
Isointense to mildly hypointense on T2-weighted images
Intense enhancement with contrast

Metastases

Hypointense on T1-weighted images, hyperintense on T2-weighted images (although variable)

Paraneoplastic limbic encephalitis

Medial temporal lobe
Hyperintense on T2-weighted images

basal parts of the skull often allows them to grow large without clinical findings other than, for example, progressive failure of intellect. Hunter *et al.* (1968) were able to report three patients with frontal meningiomas who had been mentally ill for 3, 25 and 43 years, respectively, before the correct diagnosis was made. Focal neurological signs of great importance may easily be missed owing to the intellectual enfeeblement of the patient; in particular it is difficult to assess visual fields or unilateral anosmia without the patient's full cooperation.

Most if not all these tumours would now be identified quite early in the course of the illness using CT or MRI brain scans. Nevertheless, it is instructive to consider the incorrect diagnoses that were made when clinicians did not have access to neuroimaging, and the cerebral tumour was missed. In many cases the patient was incorrectly diagnosed as suffering Alzheimer's disease or one of the other progressive dementing illnesses. This misdiagnosis is of course a special hazard in the elderly in whom dementing illness is more common. This hazard is probably compounded by the involutional cerebral atrophy of the older person. As a result, compared with a young person, space-occupying lesions can grow to a larger size before causing an increase in intracranial pressure, and so will be more easily missed (McMenemey 1941).

Cerebrovascular disease was another common misdiagnosis. In Raskin's (1956) series all 10 of the patients with meningiomas that had been missed during life were incorrectly diagnosed as suffering 'cerebral arteriosclerosis'. Evidence of arteriosclerosis on clinical examination, or a past history of focal cerebrovascular accidents, may lead the examiner to undervalue the significance of focal symptoms and signs when these exist. In addition, some tumours first declare themselves with an episode of infarction, and further investigation may then not be pursued.

Alcoholism may also be misleading. When a clear history of alcohol abuse is obtained, persistent amnesic difficulties will often be ascribed to this. Similarly, episodes of confusion in the early stages of a tumour may be mistaken for intoxication. In the following case study the diagnosis was only made because of the patient's request for a CT scan.

A man of 34 was referred because of his concern over impaired concentration and memory. He had been a severe alcoholic until 2 years previously, but since then had abstained completely. Problems with memory had been marked when drinking and had improved considerably since he stopped, but this improvement had reached a plateau. He was also aware of ready mental fatigue, and was eager to know whether brain damage due to alcoholism had persisted. His only other complaint was of episodes

of vertigo and nausea for the past 3 months, ascribed by his general practitioner to labyrinthitis. Examination showed positional nystagmus but no other neurological signs. There was no evidence of cognitive impairment on examining his mental state.

He was strongly reassured that there was little likelihood of alcoholic brain damage. Psychometric testing reinforced this conclusion, showing superior intelligence and intact memory functions. By way of further reassurance his request for a CT scan was granted. A large cystic lesion was revealed in the cerebellum, compressing the fourth ventricle and causing dilatation of the third and lateral ventricles. By the time of the scan, 1 month after presentation, he had developed ataxia of gait and papilloedema was apparent. This had not been present before. At operation a low-grade cystic astrocytoma was removed and he made an excellent recovery.

Toth *et al.* (2002) described a case in which a 46-year-old man presented with an amnesic confabulatory syndrome in the context of heavy alcoholism. The patient did not respond to intravenous thiamine. Neuroimaging revealed an enhancing mass located within the third ventricle and involving cortical and subcortical regions. Histology proved it to be a primary CNS lymphoma. There was considerable radiological reduction of the lesions following administration of dexamethasone, which unfortunately was not accompanied by clinical improvement.

Epileptic seizures may be misinterpreted as due to idiopathic epilepsy. Approximately 20% of tumours are estimated to present with epilepsy, mostly of a focal nature (see below). In psychiatric practice temporal lobe epilepsy will present a special hazard, since even the epileptic nature of the phenomena may be missed. Malamud (1967) reviewed the case histories of 18 patients coming to post-mortem in psychiatric hospitals with tumours of the limbic areas of the brain; all had been diagnosed as suffering from non-organic psychiatric illnesses, although much of the symptomatology appeared to be based in temporal lobe epilepsy that had been overlooked.

A special source of error is the readiness with which the patient's family, and his physician, are liable to interpret early symptoms in terms of current stress in the life situation. Minski (1933) found that 19 of 58 patients with cerebral tumours admitted to the Maudsley Hospital had a clear history of stress antedating admission in the form of recent accidents, bereavements or occupational difficulties. Sometimes the stress may have served to focus attention on early symptoms, or sometimes the patient's attempt to cope with the problem may have unmasked his reduced adaptability.

A man of 37 was referred by a neurologist for psychiatric treatment on account of depression and irritability of recent onset, together with panicky feelings when travelling. He had developed epilepsy 4 years earlier, after a mild head injury, but this remained well controlled by anticonvulsant medication. He also complained of intermittent headache and difficulty in concentrating on his job, but in fact was coping well and had recently been promoted. Neurological examination was entirely normal. He had always been of an anxious, pedantic disposition and prone to take his responsibility very seriously. His wife was expecting the birth of a second child and they were due to face considerable financial difficulties. He was treated with minor tranquillisers and supportive psychotherapy for 6 months, and showed improvement. Suddenly, however, he developed a hemianopia and a sixth nerve palsy, and was admitted to hospital in semicoma. A slow-growing astrocytoma in the non-dominant temporal lobe was discovered.

Dissociative and conversion disorders are a well-known source of error. Neurological signs of a puzzling or unconvincing nature readily invite this label, especially in patients with an unstable background. Certain symptoms, such as somnolence, may be viewed with suspicion when they are unsupported by physical findings. The patient who has displayed conversion symptoms in the past is especially at risk (see Chambers 1955).

Management of brain tumours

Medical management

Acute treatment may be needed to stabilise the patient with regard to peritumoral oedema and raised intracranial pressure, seizures or delirium. Other medical issues likely to need attention include managing side effects of chemotherapy and immunosuppression, and prophylaxis of venous thromboembolism. When the hypophysis is affected, endocrine deficiencies may need to be treated. Additionally, a package of supportive care aimed at providing a good quality of life should be considered.

Seizures are the presenting symptom of brain tumours in approximately 20% of patients and may be present at some stage of the illness in 62% or more of patients (Wen & Marks 2002). Supratentorial tumours located within or near the cortex tend to have a higher incidence of seizure activity; younger patients and those with more aggressive tumours or malignancies are most at risk. Treatment is with standard antiepileptic drugs, acknowledging that the epilepsy is focal or secondary generalised. Given that the patient is likely to be on other drugs that are metabolised by the hepatic micro-

somal cytochrome P450 system, including dexamethasone and some of the chemotherapeutic agents, antiepileptics with less interaction with the cytochrome system, like levetiracetam and gabapentin (Vecht *et al.* 2003), may be preferred. Patients with a brain tumour are likely to be sensitive to the effects of antiepileptic drugs. The cognitive impairments that may result from antiepileptic drugs, such as slowing of mental performance, sedation and fatigue, are common symptoms of brain tumours *per se*. Therefore the lowest effective dose and monotherapy, as opposed to polytherapy, are preferred (Meador 1994). Prophylactic use of antiepileptics in patients with brain tumour who are asymptomatic is unnecessary; even in patients who have had a craniotomy, the value of prophylactic antiepileptic medication to reduce the frequency of seizures is unclear (Glantz *et al.* 2000).

For the management of peritumoral oedema and raised intracranial pressure, dexamethasone is the preferred high-potency steroid. It has little mineralocorticoid activity and possibly a lower risk of infection and cognitive impairment compared with other corticosteroids (Wen & Marks 2002). The dose will depend on tumour histology, location, size and amount of peritumoral oedema, and may be limited by the development of complications of steroid treatment. These include peptic ulceration, particularly in the elderly and those with a history of peptic ulcers. Steroid myopathy occurs in 2–21% of brain tumour patients on treatment; again the elderly are more at risk. The clinician also needs to be aware of the risk of *Pneumocystis carinii* pneumonia (PCP), a risk that will be aggravated by other immunosuppressant treatment. Some recommend monitoring of CD4⁺ cells as a marker of risk, and for those patients at greatest risk prophylactic anti-PCP treatment (Kumar & Krieger 1998). Other complications of dexamethasone include sleep disturbance, delirium or psychosis, and osteopenia.

All oncological patients have an increased risk of thromboembolism (deep vein thrombosis) and pulmonary embolism. For patients with brain tumours, the risk of deep vein thrombosis and pulmonary embolism is higher than in the general cancer population (Hamilton *et al.* 1994; Deitcher & Gomes 2003). It may be appropriate for some patients to receive prophylactic low-molecular-weight heparins, although any benefit may be outweighed by the increased risk of intracranial bleeding (Wen & Marks 2002).

A variety of endocrine deficits may be seen in patients with tumours located in the hypothalamo-pituitary area and in patients treated with radiotherapy. When present these will require expert assessment and treatment (Swensen & Kirsch 2002). Apathy, fatigue and low mood not amounting to depression may coexist and be the result of the hemispheric and diencephalic dysfunction accompanying the pituitary disease. It has been suggested that in such patients it is important to identify any abnormalities of the hypothalamic-pituitary axis and treat it accordingly (Weitzner *et al.* 2005).

Management of psychiatric sequelae

Many patients with brain tumours will need treatment for their depression and anxiety. Appropriate treatment of a depressive illness may improve quality of life and functional outcome (Mainio *et al.* 2003). Attention should be paid to suicidal ideation and risk, as cancer patients are at increased suicidal risk compared with the general population, especially when in pain and during the end-stages of the illness (Breitbart 1995). Once the diagnosis of depression is established, the choice of antidepressant will depend heavily on the propensity for side effects. Generally, the selective serotonin reuptake inhibitors (SSRIs) are the drugs of choice (Pirl & Roth 1999; Schwartz *et al.* 2002). Psychological interventions such as supportive psychotherapy and cognitive-behaviour techniques in combination with pharmacotherapy have been recommended, although the evidence base for effectiveness is not robust (Newell *et al.* 2002). Anxiety is common and is often associated with depression. Exacerbation of premorbid traits may become manifest. Behavioural interventions such as relaxation training, systematic desensitisation and imagery techniques may be of benefit for some patients (Redd *et al.* 2001). Pharmacotherapy, for example benzodiazepines, may be indicated when the levels of anxiety and distress are high.

Cognitive impairment is an important indicator of prognosis and may also help the clinician to choose the treatment of choice with regard to the risks and benefits of new treatment regimens and their potential neurotoxicity (Meyers *et al.* 2000a). As noted above, cognitive deterioration may be an early marker of tumour progression. Serial neuropsychological testing may therefore be necessary, bearing in mind that patients with cerebral tumours are unlikely to tolerate prolonged testing (Meyers 2000). The choice of cognitive test will depend on the setting and will range from the Mini-Mental State Examination to more comprehensive functional tests. A hierarchical approach, taking about 1 hour to complete, has been proposed (Taphoorn & Klein 2004).

It has been suggested that methylphenidate may improve cognition. In a controlled trial of 30 patients, improvements in stamina, bladder control and cognitive function were seen in about half while on methylphenidate (Meyers *et al.* 1998). This was despite the fact that in some there was progressive tumour growth documented on MRI. A randomised, double-blind, cross-over study of children who had been treated with chemotherapy or radiotherapy to the CNS for brain tumour ($N = 43$) or acute lymphoblastic leukaemia ($N = 40$) found beneficial effects of methylphenidate on attentional and social deficits reported by teachers and parents (Mulhern *et al.* 2004). Unfortunately, the results are not presented in such a way that it is possible to single out only those with brain tumours.

Palliative care will be an important aspect of management. Disabling neurological symptoms like dysphagia will need

careful attention, and adequate pain control needs to be available. Carers will need support. Hospice care provision may be needed for some terminally ill patients. All will require conscientious attention to the ethical, existential and spiritual matters at the end of life.

Management of the tumour

The specific management of brain tumours goes beyond the scope of this chapter. However, some of the recent therapeutic developments are discussed, placing special emphasis on the neuropsychiatric consequences of receiving such treatments.

Chemotherapy

The sensitivity of the cerebral tumour to chemotherapy depends on the histology. Medulloblastomas, lymphomas, oligodendrogliomas and germ cell tumours are significantly chemosensitive. Recently, the alkylating agent temozolamide has been shown to be effective in oligodendroglial tumours, oligoastrocytic tumours and anaplastic astrocytomas in terms of both progression-free and overall survival (Taphoorn & Klein 2004). Chemotherapy is more effective when there is less tumour present and therefore it is usually administered following radiotherapy or surgery; however, it can be used either concurrently or as initial therapy depending on the functional status of the patient (Mathieu & Fortin 2006). Aggressive tumours may require combination chemotherapy.

Neurotoxicity is a troublesome side effect of chemotherapy and is more likely when drugs are administered intravenously, and especially intrathecally. For example, intrathecal methotrexate can produce a necrotising encephalopathy (Brock & Jennings 2004). Temozolamide may produce headaches, seizures and neurological deterioration. Cisplatin may cause encephalopathy as well as peripheral neuropathy (Steeghs *et al.* 2003). Intra-arterial carmustine may cause central neurotoxicity with imaging and pathological features similar to late radiation necrosis (Taphoorn & Klein 2004). The risk of developing cognitive side effects is increased when radiotherapy precedes or is given concomitantly with chemotherapy (Taphoorn & Klein 2004).

Surgery

Neurosurgical treatment may be needed at an early stage to establish the histological diagnosis. In some cases it will be necessary to reduce the size of the tumour to alleviate symptoms of raised intracranial pressure, whereas in others the neurosurgeon will attempt complete resection. However, neurosurgery may result in damage to otherwise healthy peritumoral tissue, as well as tissue along the path of access to the tumour. The neurosurgeon may therefore be reluctant to operate if the tumour is near eloquent areas of the brain (Taphoorn & Klein 2004). However, Duffau *et al.* (2003) oper-

Box 5.2 Factors associated with radiation-induced deficits

- Radiation factors: total dose, fractional dose, total duration of therapy, volume of brain irradiated
- Patient factors: age, genetic predisposition, pre-existing neurological diseases (e.g. multiple sclerosis), systemic diseases and concomitant radiotherapy
- Endocrine dysfunction secondary to radiation damage to the hypothalamic–pituitary axis, resulting in adrenal, thyroid and growth-hormone deficits

ated on 77 patients with low-grade gliomas who did not have apparent clinical deficits despite the fact that there was evidence of tumour invasion of primary sensory and/or motor areas or language areas. All patients showed clinical deficits postoperatively, although complete recovery occurred within 3 months in 73 cases. In patients whose cerebral blood flow may be compromised by raised intracranial pressure, the neurosurgeon will be concerned about the general risks of anaesthesia.

As mentioned above, some children undergoing resection of posterior fossa tumours suffer a syndrome of cognitive impairment and affective symptoms. The postoperative cognitive dysfunction in children with cerebral tumours has been delineated in a study of 106 children within 3 months after surgery for different tumours (craniopharyngioma, low-grade glioma, ependymoma and optic glioma) prior to stereotactic radiotherapy. A discrepancy between verbal and performance IQ scores, with performance IQ being consistently lower than verbal IQ, was detected in 45% of the patients and lower performances in the language, visuospatial and motor domains in 20–30% (Carpentieri *et al.* 2003).

Radiotherapy

Cognitive deficits attributed to radiotherapy have been reported in children receiving radiotherapy to the brain for acute leukaemia or brain tumours; greater impairment is found in females (Sarkissian 2005). Problems are also observed in adults years after prophylactic irradiation of the brain for gliomas, brain metastases, primary CNS lymphoma, nasopharyngeal malignancies or small-cell lung carcinoma (Taphoorn & Klein 2004). The factors associated with radiation-induced deficits are shown in Box 5.2.

Vascular damage and demyelination are the main features of radiation damage. Vascular abnormalities initially consist of transient perivascular lymphocytic infiltrations which then lead to progressive vascular alterations with haemorrhage and necrosis. Demyelination with subsequent breakdown of the myelin sheath occurs when oligodendrocytes are damaged (Peissner *et al.* 1999; Belka *et al.* 2001). Various pathophysiological hypotheses have been proposed to explain the damage (Box 5.3).

Box 5.3 Mechanisms of radiation neurotoxicity

- Ionising damage to the genetic structure of cells, particularly oligodendrocyte progenitor cells. Radiation breaks the DNA strands and attacks RNA, proteins and lipids (Abrey & Correa 2005). Because radiation-induced damage leads to demyelination in the white matter, oligodendrocytes might be a potential target. Damage to the ability of oligodendrocyte progenitors to reproduce and replace mature myelin-producing oligodendrocytes may have a pathogenetic effect (Van der Maazen *et al.* 1991)
- Vascular endothelial damage, with subsequent ischaemia. However, the degree of necrosis of the neural tissue is often greater than expected for the amount of vascular damage
- Radiation interrupts cellular proliferation and kills dividing cells. This occurs particularly in rapidly dividing cells rather than cells in S phase (New 2001). It may also lead to apoptotic cell death (Peissner *et al.* 1999)

Some patients develop an acute radiation encephalopathy within 2 weeks, caused by vasogenic oedema and disruption of the blood–brain barrier. Characteristic symptoms include headache, somnolence, and worsening of neurological symptoms that were already present. This acute encephalopathy improves with corticosteroids. About 1–6 months after completion of radiotherapy, patients may develop an early-delayed radiation encephalopathy which may be difficult to distinguish from early tumour progression. Drowsiness, worsening of neurological symptoms and transient cognitive deficits consisting of short-term memory and attentional deficits are seen. It may resolve completely after 6–12 months (Lewanski *et al.* 2000; Armstrong *et al.* 2002; Taphoorn & Bromberg 2005). Late-delayed encephalopathy is serious and irreversible. It may take the form of local radionecrosis or diffuse leucoencephalopathy and cerebral atrophy (Taphoorn & Klein 2004). There is an association between the severity of cognitive deficits and imaging abnormalities such as cerebral atrophy and leucoencephalopathy (Postma *et al.* 2002). Memory, attention and new learning, as well as processing speed are sensitive to radiotherapy. Common neurological sequelae include urinary incontinence, ataxia, and pyramidal as well as extrapyramidal signs. MRI may show diffuse atrophy with ventricular enlargement as well as severe confluent white matter abnormalities on T2-weighted MRI (Monje & Palmer 2003; Taphoorn & Klein 2004). Meyers *et al.* (2000b) followed 19 patients with basal skull tumours who had received paranasal sinus radiotherapy between 20 months and 20 years earlier. More than half of the patients had difficulty in learning new information and 80% displayed accelerated forgetting over time. Additionally, one-third of the patients displayed deficits of visuomotor speed, frontal lobe

executive function and fine motor coordination. Two of the patients had severe necrosis with ensuing dementia and blindness (Meyers *et al.* 2000b). Klüver–Bucy syndrome has been described in a 58-year-old woman who received postoperative radiotherapy for a craniopharyngioma, with extensive bilateral mesial temporal necrotic lesions (Benito-León & Domínguez 1998).

Improvements in technology aim to deliver high doses of radiation to the tumour while significantly sparing the surrounding healthy structures. Intensity-modulated radiation therapy (IMRT) generates small modulated radiation beams that strike a tumour with varying intensities and from many angles to attack the target in a complete three-dimensional manner. Stereotactic surgery combines the principles of stereotactic localisation with precise delivery of radiation to an imaging-defined target. The gamma knife uses emitted photons that are directed precisely through circular channels drilled into a high-density metal helmet. Linear accelerator-based radiosurgery (LINAC) uses a stereotactic head frame and a 6-MeV linear accelerator, while the cyberknife has a compact lightweight linear accelerator mounted on a robotic arm. These methods are all efficacious and offer a more circumscribed approach to the treatment of brain tumours (Brown & Pollock 2005).

New therapeutic modalities

Novel therapeutic approaches targeted at the aetiological factors that may be responsible for tumours, especially gliomas, have been developed. They are being used as adjuvant therapy in combination with other treatments.

- Gene therapy (Hutterer *et al.* 2006): viral genes are delivered to the malignant cells, rendering them susceptible to the effects of antiviral drugs, which block their proliferation.
- Signal transduction inhibitors (Sathornsumetee & Rich 2006) aim to reverse the abnormal activation or suppression responsible for the resistance to radiotherapy.
- Immunotherapy, particularly the use of monoclonal antibodies directed against antigens expressed by glioma cells (Akabani *et al.* 2005). Interferons are also being used (Hoang-Xuan & Delattre 1996).
- Tamoxifen, a hormonal treatment that inhibits and modulates PKC (an enzyme involved in cellular signal transduction), may have a role (Mastronardi *et al.* 1998).
- Stem cell therapy (Yuan *et al.* 2006) aims to deliver molecules capable of enhancing antitumour immunity or altering their genetic structure.

These are all promising strategies in the earlier stages of development for clinical practice.

Epilepsy

John D.C. Mellers

Maudsley Hospital, London

The manifestations of epilepsy include facets of equal importance to the psychiatrist and the neurologist. Some aspects indeed stand firmly at the junction between the two disciplines. The seizure itself may take the form of the classic motor convulsion or consist instead of complex abnormalities of behaviour and subjective experience. Associated disorders may sometimes include cognitive difficulties, personality disturbances or psychotic illnesses of various types and durations. In all these respects the study of patients with epilepsy has played an important part in advancing our knowledge of brain function and dysfunction, and in indicating something of the pathophysiological basis for certain forms of psychological disorder.

The accent in this chapter is on those aspects most relevant to the work of the psychiatrist. It is now clear that the great majority of people with epilepsy suffer little or no mental disturbance, but those who do can present difficult and complicated problems. Psychosocial and organic factors are often inextricably mixed in causation, and assessment of all the evidence available in the individual patient can be a complex and time-consuming matter.

Classification of seizures and epilepsies

Chadwick (1994) recommends defining an *epileptic seizure* as 'an intermittent, stereotyped disturbance of consciousness, behaviour, emotion, motor function or sensation that on clinical grounds is believed to result from cortical neuronal discharge'. This definition conveys three important principles: (i) that the core presenting feature, the seizure, is a transient abnormality of neurological function that is highly uniform from one episode to the next; (ii) that the diagnosis depends primarily on clinical judgement; and (iii) that the underlying mechanism of an epileptic seizure is an abnormal cortical discharge. The term *epilepsy* denotes a condition in which there are recurrent epileptic seizures (unless they arise in the

context of a reversible toxic or metabolic state). Although a diagnosis of epilepsy implies that symptoms are the result of abnormal electrical activity, this may in turn have many different causes. Thus, epilepsy must always be regarded as a symptom rather than a disease. It is a sign of abnormality within the central nervous system (CNS) that requires further elucidation.

The current classification of epilepsy (Commission on Classification and Terminology of the International League Against Epilepsy 1981, 1989) approaches the subject at two levels: (i) there is a system for classifying seizures based on clinical signs and symptoms (i.e. semiology), and (ii) there is a classification of epileptic syndromes. The latter is derived from the classification of seizures, but in addition takes into account patterns of signs and symptoms, age at onset, electrophysiological findings, natural history and factors of potential aetiological significance, including background and family history and pathology where known. It represents an attempt to define syndromes that are homogeneous with respect to aetiology and which have practical implications for treatment and prognosis. It is an imperfect and evolving nosology. With advances in our understanding of pathophysiology, and perhaps the genetics of epilepsy in particular, future refinements to this system are both inevitable and desirable.

Classification of seizures

The International League Against Epilepsy (ILAE) system for classifying epileptic seizures is shown in Table 6.1. The most important division distinguishes between seizures that arise from epileptic discharges beginning in a circumscribed brain region (*partial seizures*) and seizures that have no detectable focal onset and seemingly involve the cortex bilaterally from the start (*generalised seizures*). A third category of unclassified or mixed seizure types is included in recognition of

Table 6.1 International classification of epileptic seizures. (Adapted from Commission on Classification and Terminology of the International League Against Epilepsy 1981 with permission.)

I	Partial seizures
A	Simple partial seizures
B	Complex partial seizures
C	Partial seizures evolving to secondarily generalised seizures
II	Generalised seizures
A1	Absence seizures
A2	Atypical absence seizures
B	Myoclonic seizures
C	Clonic seizures
D	Tonic seizures
E	Tonic-clonic seizures
F	Atonic seizures
III	Unclassified epileptic seizures

rare cases in which classification is uncertain. A description of the main clinical characteristics of seizure types is given in the next section to provide an overview of seizure semiology. Further detail about specific semiological features and their localising value is given in the section covering the localisation-related epilepsy syndromes. A glossary of terms used to describe seizures is provided by the ILAE (Blume *et al.* 2001).

Partial seizures

The term 'partial' in the current classification system replaces the older terms 'focal' and 'focal-onset'. Partial seizures occur when an epileptic discharge arises from a localised region of a single cerebral hemisphere. Partial seizures are subclassified according to whether consciousness is fully retained throughout (*simple partial*) or impaired (*complex partial*) and whether they evolve to become a generalised seizure.

Simple partial seizures

During a simple partial seizure the patient remains fully conscious and is therefore usually able to provide a description of the attack. The symptoms at the beginning of the seizure are of great importance as they may indicate which area of the brain is involved at the onset of the epileptic discharge. Any neurological function may be affected but motor signs are the most frequent. The most common form of simple partial seizure is a motor seizure arising from the primary motor cortex. This gives rise to regular, rhythmical, jerking (clonic) movements in the group of muscles corresponding to the affected area in the cortex. If the seizure discharge spreads, it does so along the motor strip moving between adjacent regions of the motor homunculus. This phenomenon was first described by Hughlings Jackson and focal motor seizures of this type are known as *Jacksonian motor seizures*. The progression to adjacent muscle groups is known as

a *Jacksonian march*. Other motor signs, including dystonic posturing and complex behavioural automatisms, are more common in complex partial seizures. A special variety of dystonic posturing in which there is sustained rotation of the head and neck, sometimes accompanied by version of the eyes into lateral gaze, may be referred to as an *adversive seizure*. The direction in which the head and eyes move at seizure onset is a moderately reliable lateralising sign, with both moving away from the hemisphere in which the discharge begins. Partial motor seizures may sometimes be followed by a transient paralysis (*Todd's paresis*), which may last from minutes to several hours. Vocalisations and sudden cessation of speech are further examples of motor phenomena. With respect to sensory experiences, an important principle is that when the epileptogenic focus is sited in primary sensory cortex, the patient experiences elementary sensory symptoms. In contrast, seizures arising in neocortical regions with a higher-order integrating sensory function, for example temporoparietal areas, result in more complex illusions and hallucinations. Thus, seizures arising in the first postcentral gyrus evoke somatosensory symptoms such as tingling, pins and needles, electrical sensations and numbness which, like their motor counterpart, may show Jacksonian progression. Similarly, seizures arising in the primary visual or auditory cortex are associated with elemental hallucinations: in the case of the primary visual cortex, flashing lights, simple shapes and patterns are commonly described, while buzzing and hissing sounds are examples of symptoms associated with epileptic foci in the primary auditory cortex (middle temporal gyrus). Olfactory and gustatory experiences are usually unpleasant (burning, metallic) or difficult for the patient to characterise, and are associated with seizures arising in the limbic system. A relatively common symptom, sometimes known as a *cephalic aura*, is the experience of an indescribable sensation in the head. Symptoms classified as autonomic by the ILAE include some of the most common epileptic symptoms. Most notably, the classic *epigastric aura*, which comprises a sensation of 'butterflies in the stomach', beginning in the epigastrium and then rising up the chest. This is most commonly associated with medial temporal lobe foci. Other autonomic symptoms include changes in heart rate, blood pressure, perspiration, piloerection, 'goosebumps' and mydriasis. These symptoms arise when midline basal brain structures are involved in seizure discharge.

Of particular interest to psychiatrists are the symptoms described as psychic in the ILEA classification. Cognitive symptoms include dysphasia and various distortions of memory (dymnesic symptoms) such as *déjà vu*, a vivid sense that everything has happened before, *jamaïs vu*, a sense that everything suddenly seems unfamiliar and new, and *panoramic memory*, in which the patient relives an experience from their past played back rapidly in the mind's eye. Patients may experience distortions of thought such as *forced thinking*,

which describes a feeling of being compelled to think about a specific topic or word; or *crowding of thoughts*, which describes a feeling of racing, disorganised thoughts. Subtle but disturbing changes in the quality of perception are reported, including derealisation and depersonalisation, distortions in the perception of time and changes in the significance of objects. These latter are often impossible for patients to describe but may involve a sense that a specific object in their environment seems changed and has a heightened but mysterious personal relevance. Affective symptoms are usually unpleasant and include fear, dysphoria, sadness and feelings of unworthiness or guilt. Occasionally mood changes are pleasurable. Illusions and complex fully formed hallucinations in all modalities may occur. Patients usually retain insight into the illusory nature of their misperceptions.

Simple partial seizures are brief, usually lasting for a few seconds only and rarely for more than 2 minutes. Scalp electroencephalography (EEG) during a simple partial seizure (ictal EEG) is usually entirely normal (Devinsky *et al.* 1988) and thus is usually not helpful in differentiating simple partial seizures from psychiatric presentations such as dissociative seizures, panic attacks or psychotic symptoms.

Complex partial seizures

Complex partial seizures are partial seizures that involve some degree of impaired consciousness. In most complex partial seizures, however, the patient is fully aware for a few seconds at seizure onset. In these cases patients experience symptoms at the beginning of a complex seizure, known as an *aura*, that may include any of those associated with simple partial seizures described above. In some 20% of cases patients report no aura, indicating either that consciousness was impaired from the start or that the patient has no memory of any premonitory symptoms after the seizure. Subtle degrees of impaired consciousness may be difficult to determine, especially in the presence of dysphasia or overwhelming affective experiences and indeed this is a criticism that has been levelled at the current system of classification. Although the defining characteristic of complex partial seizures is that consciousness is impaired at some stage of the seizure, unconsciousness – with loss of axial muscle tone, a fall and complete unresponsiveness – is not implied. Rather there is clouding of consciousness during which the patient will appear confused, disoriented and preoccupied but may interact with people and handle objects in their immediate environment, albeit in a disorganised manner and in ways that are inappropriate to the immediate social context. To the observer there is an inconspicuous and gradual transition from normal alertness to impaired responsiveness. Recovery, likewise, is almost never abrupt. During the phase of impaired consciousness the patient commonly engages in repetitive semi-purposeful activities known as *automatisms* [Classification of epilepsy syndromes (Anatomically defined localisation-related epilepsy syndromes) and Epileptic

automatisms (under Classification of psychiatric syndromes in epilepsy)]. The most common are oro-alimentary automatisms, which include lip-smacking, chewing and swallowing movements. Repetitively picking at, or adjusting, clothing or handling objects within easy reach are also frequent (gestural automatisms). Vocal automatisms may include perseverative utterances (sometimes called epileptic pallilalia), humming, singing and laughing (*gelastic seizures*). The laughter in gelastic seizures typically has an unusual quality, is not infectious and seems mirthless. Wandering is common (ambulatory automatisms) and may seem semi-purposeful, as if the patient is searching for something or trying to escape, or may involve walking in circles (*cursive seizures*) or running. Although impairment of consciousness has conventionally been regarded as a necessary condition for the emergence of automatisms, isolated cases have been reported in which automatisms have occurred while the patient remained fully alert and responsive during clearly documented simple partial seizures (Alarcon *et al.* 1998; Biraben *et al.* 2001). The ictal EEG in complex partial seizures reveals unilateral or frequently bilateral epileptiform discharges most commonly in the temporal or frontotemporal regions.

Partial seizures with secondary generalisation

Approximately 60% of patients with partial seizures will experience a secondary generalised seizure at some point. Occasionally, patients have secondarily generalised seizures with almost every partial seizure. In such cases the generalised convulsion may be so dramatic that it overshadows the preceding partial seizure. For this reason, when a patient presents with apparent generalised seizures, care must always be taken to search for any evidence of a partial seizure onset: from the patients themselves, who should be questioned about aura symptoms, and from witnesses who should be asked about blank staring episodes or brief automatisms occurring before the convulsion.

Generalised seizures

The defining characteristic of generalised seizures is that they have no detectable focal onset: the abnormal electrical discharges that accompany clinical seizures involve the cerebral cortex bilaterally at onset. Competing hypotheses have proposed that the primary abnormality, conceived of as hyperexcitability, might lie in the cortex or in a subcortical ‘centrencephalic’ system (i.e. brainstem reticular formation and the nuclei of the diffuse thalamic projection system), a debate that has not yet been resolved (Avoli *et al.* 2001). Generalised seizures are divided into six sharply differing forms: absence (*petit mal*), myoclonic, tonic-clonic, tonic, clonic and atonic, as described below. This classification is based on the marked clinical differences between each type of seizure, but each seizure type is also accompanied by characteristic EEG findings. This presumably reflects distinct underlying pathophysiology, but the nature of this is poorly understood,

as indeed are the mechanisms that link EEG abnormalities with clinical semiology.

Absence (*petit mal*) seizures

Absence (*petit mal*) seizures begin in childhood or adolescence and disappear in 80% of cases by adulthood, or are replaced by generalised tonic-clonic seizures. They rarely occur *de novo* in adults (see Generalised epilepsy and Non-convulsive status epilepticus (Absence status) later in chapter). Without warning the patient loses contact with the environment, usually for 4 or 5 seconds but occasionally for as long as half a minute. To the onlooker the patient appears momentarily dazed, stops speaking and becomes immobile. The face is pale, the eyes assume a glazed appearance and the pupils may be observed to be fixed and dilated. Posture and balance are usually well maintained, though muscular relaxation may allow the head to slump forward. Brief muscular twitches may be seen around the eyes, occasionally extending to brief myoclonic jerks of the limbs. Such movements are bilateral and symmetrical. Consciousness is typically deeply impaired during the attack, though in rare cases subjects may remain dimly aware of what is happening around them. There are usually no after-effects. The patient may later be aware of the attack as a momentary break in the continuity of events, but quite often does not know it has occurred and continues immediately with the sentence or activity that was interrupted. While each attack is brief, runs of attacks sometimes occur in rapid succession. The frequency of episodes is commonly five to ten per day, but sometimes hundreds may be noted in the course of a single day. In such cases individual seizures may be so fleeting and inconspicuous that the disorder only comes to light because of a decline in a child's performance at school. Lennox (1960) suggested that if attacks do not occur daily, the diagnosis should be questioned.

Atypical absences show more protean manifestations, yet are accompanied in the main by the EEG features of simple absences. They begin and end abruptly like typical absences but the duration of attacks is likely to be longer, and they are often accompanied by prominent increases or decreases in muscle tone and tonic activity (Holmes *et al.* 1987). They are more likely to occur in patients with developmental delay and additional seizure types, and the interictal EEG is more frequently abnormal. However, typical and atypical absences seem not to be discrete entities, but rather form parts of a continuum. In 'absence with automatism' there may be lip-smacking, chewing, mouthing or fumbling movements, even brief aimless walking, and vocalisations may occur. Such automatisms can present difficulty over clinical differentiation from brief temporal lobe seizures, particularly when the latter are partially controlled by drugs. Close observation of the content of the attacks and the EEG picture usually serve to make the distinction, but sometimes even the latter will yield inconclusive results. In such circumstances one may ultimately be forced to a trial of different medications (Marsden & Reynolds 1982).

Tonic-clonic seizures

Tonic-clonic seizures (formerly known as grand-mal seizures) of the primary generalised type occur without immediate warning and consciousness is lost abruptly. However, some subjects may be aware that a fit is imminent on account of ill-defined symptoms (the *prodrome*, see Pre-ictal disorders, later in chapter) present for hours or even days before the seizure, such as irritability, sleep disturbance, anxiety, nausea or headache. In subjects liable to myoclonic jerks these may increase in frequency for some hours before the tonic-clonic seizure. The seizure consists of a tonic followed by a clonic phase that involves all parts of the body symmetrically and from the same moment. During the tonic phase there is first flexion then extension of the axial muscles, rapidly spreading to the limbs. Forced exhalation may be accompanied by vocalisation in the form of a moan or cry. Disruption of respiration may lead to cyanosis. Eyes remain open, are deviated upwards and the pupils dilated. As the clonic phase begins, muscular rigidity is gradually replaced by generalised jerking movements that are regular and synchronous in all four limbs. Initially, the convulsive movements are fast (8 Hz) and appear tremulous but they gradually slow to around 4 Hz. Respiration becomes laboured and saliva may be extruded through closed teeth, giving the appearance of frothing at the mouth. Patients may injure themselves by falling at seizure onset, may bite their tongue or inside of their cheek at the beginning of the clonic phase, and may be incontinent during either the tonic phase or in the immediate postictal period. Compression fractures of the vertebrae may occur in the tonic phase but are often asymptomatic. The seizure is usually followed by a deep sleep, which may then be succeeded by nausea, vomiting and headache. If sleep does not occur, a period of confusion is usually seen before full consciousness is regained. During this period the patient is disorientated, often restless, rambling and incoherent, and sometimes unaware of his personal identity. On recovery there is total amnesia for the content of the attack and frequently for a period of several seconds extending in a retrograde direction. Most tonic-clonic seizures last for less than 1 minute. Occasionally, especially with treatment, very brief seizures are followed by rapid recovery with little postictal confusion.

Tonic and clonic seizures

Tonic and clonic seizures may occur in isolation. Tonic seizures simply resemble the tonic phase of a tonic-clonic seizure as described above. They most commonly occur in sleep and recovery is typically abrupt with little postictal confusion. Slowly evolving changes in tone are occasionally seen as are versive movements. Isolated clonic seizures begin with a sudden loss of consciousness, loss of muscle tone and a fall.

Myoclonic seizures

The term 'myoclonus' may be used in a generic sense and refers to shock-like involuntary movements arising through

a variety of neurological mechanisms which, in addition to epilepsy, may include disorders of the spinal cord, cerebellum and brainstem. In the context of epilepsy, myoclonic seizures are sudden shock-like movements, lasting for only a fraction of a second, affecting mainly the neck, arms and shoulders. Objects that are being held may be dropped or flung violently. If the trunk or legs are affected, the patient may be thrown off balance. Seizures are often bilateral but not necessarily so and a single limb or even a single muscle group may be affected. It is uncertain whether consciousness is lost or retained, since the seizures last for so very short a time, but myoclonic seizures occurring in rapid succession may be associated with impaired awareness and responsiveness. Single myoclonic jerks frequently occur in subjects suffering from absences or atonic seizures. Benign myoclonic jerks may also be seen in normal individuals when falling asleep. Myoclonic seizures are a defining characteristic of juvenile myoclonic epilepsy (see below). They may also be symptomatic of several serious brain diseases. They are a characteristic feature of subacute encephalitis, the cerebral lipidoses and Creutzfeldt–Jakob disease. Rare progressive forms of myoclonic epilepsy, which may be associated with progressive ataxia or dementia, include Unverricht–Lundborg disease and Lafora body disease (Epilepsy occurring in hereditary disorders, later in chapter).

Atonic seizures

Atonic seizures involve a sudden loss or diminution of muscle tone, resulting in precipitate muscular relaxation affecting the head, trunk, jaw or limbs. Attacks occur without warning and last for a few seconds only. After-effects, other than those due to bruising or emotional shock, do not occur. *Astatic seizure* is a term that has come into widespread use since the 1981 ILAE classification. It refers to seizures in which the main, if not only, manifestation is loss of erect posture and a fall. The term reflects a growing realisation that such attacks occur in different forms of epilepsy and that pure atonic seizures as defined in the classification system are uncommon (Egli *et al.* 1985). Thus, sudden hypotonic falls may follow generalised myoclonic seizures (myoclonic–astatic seizures) or brief tonic seizures or may occur in patients with tonic–clonic seizures, when they represent unusually brief and abortive forms of major seizure discharges. Finally, astatic seizures have been documented as a late development in patients with intractable temporal lobe epilepsy (Gambardella *et al.* 1994). The term ‘drop attack’ is sometimes regarded as synonymous with astatic seizure, but the former may be used as a generic term to describe a sudden fall without conspicuous impairment of consciousness that may have causes other than epilepsy such as certain forms of syncope and cataplexy (see Differential diagnosis of epilepsy, later in chapter, covering the differential diagnosis of epilepsy).

Unclassifiable and mixed forms of epileptic seizures

In some patients the most careful investigation will fail to clarify the precise nature of attacks and seizures will defy

attempts at classification. Certain neonatal seizures fall into this category.

Classification of epilepsy syndromes

The ILAE classification of epilepsy is an attempt to classify epileptic syndromes by aetiology (Table 6.2). Two levels of classification are employed. Firstly, syndromes are divided into *localisation-related* or *generalised* depending on whether underlying pathology is known or suspected to be focal or general. Secondly, a classification based on known, presumed or likely aetiology is made. In relation to the first level of classification, the term ‘localisation-related’ is preferred to ‘partial’ to avoid connotations that a syndrome is incomplete in some way. Although this aspect of the syndromic classification mirrors the division of seizures into partial and generalised, it should be emphasised that it is intended as a definition based on whether or not pathology is focal, not simply on whether the seizures seen in the syndrome are partial or generalised: partial seizures may occur in patients with a symptomatic generalised epilepsy and partial seizures may secondarily generalise in localisation-related epilepsy. The second level of classification defines three classes of aetiology: ‘symptomatic’ denotes an identified aetiology; ‘idiopathic’ denotes unknown aetiology; and ‘cryptogenic’ is used in relation to syndromes that seem so strikingly uniform that a specific aetiology is suspected or presumed. The idiopathic designation is more precisely defined as epilepsy arising as a primary or autochthonous disorder (arising of itself) and includes syndromes known or likely to have a genetic basis. The system of classifying epilepsy syndromes is widely recognised as imperfect and evolving, with substantial revisions expected in the near future. Revisions are especially likely with developments in our understanding of the genetic basis of epilepsy (Engel 2001). Nevertheless, in clinical practice the current classification represents a valuable framework against which an individual patient’s clinical history should be considered in order to guide treatment decisions and advice about prognosis.

Localisation-related epilepsy syndromes

Modern investigations, particularly magnetic resonance imaging (MRI), will identify a specific aetiology in the majority of patients with partial seizures, who may therefore be classified as having symptomatic localisation-related epilepsy. In most patients without an identifiable lesional basis for their epilepsy, a combination of localising semiological features and/or focal electrophysiological findings will lead to the assumption that a cause is present but eludes identification. These cases would therefore be regarded as cryptogenic. In relation to the idiopathic syndromes, it should be noted that a number of inherited syndromes of localisation-related epilepsy, for example autosomal dominant nocturnal frontal lobe epilepsy (see Genetic basis of epilepsy, later in

Table 6.2 International classification of epilepsies and epileptic syndromes. (Modified from Commission on Classification and Terminology of the International League Against Epilepsy 1989 with permission.)

1 Localisation-related (local, focal, partial) epilepsies and syndromes

1.1 Idiopathic

Benign childhood epilepsy with centrotemporal spikes

Childhood epilepsy with occipital paroxysms

Primary reading epilepsy

1.2 Symptomatic

Chronic epilepsy partialis continua of childhood (Kojewnikoff's syndrome)

Syndromes characterised by seizures with specific modes of precipitation

Temporal lobe epilepsy

Frontal lobe epilepsy

Parietal lobe epilepsy

Occipital lobe epilepsy

1.3 Cryptogenic

2 Generalised epilepsies and syndromes

2.1 Idiopathic (with age-related onset)

Benign neonatal familial convulsions*

Benign neonatal convulsions*

Benign myoclonic epilepsy in infancy*

Juvenile absence epilepsy (pyknoepilepsy)

Childhood absence epilepsy

Juvenile myoclonic epilepsy (impulsive petit mal)

Epilepsy with grand mal seizures on awakening

Other generalised idiopathic epilepsies

Epilepsies with seizures precipitated by specific modes of activation

2.2 Cryptogenic or symptomatic

West syndrome

Lennox–Gastaut syndrome

Epilepsy with myoclonic–astatic seizures

Epilepsy with myoclonic absences

2.3 Symptomatic

2.3.1 Non-specific etiology

Early myoclonic encephalopathy*

Early infantile epileptic encephalopathy with suppression-burst*

Other symptomatic generalised epilepsies not defined above

2.3.2 Specific syndromes

Epileptic seizures complicating other disease states

3 Epilepsies and syndromes undetermined, whether focal or generalised

4 Special syndromes

4.1 Situation-related seizures

Febrile convulsions

Isolated seizures or isolated status epilepticus

Seizures occurring only when there is an acute metabolic or toxic event due to factors such as alcohol, drugs, eclampsia, non-ketotic hyperglycaemia

* Syndromes confined to the neonate or early infancy are not considered further here.

chapter), are not included in the current classification as they had not been described when it was published.

Idiopathic localisation-related epilepsy

Benign childhood epilepsy with centrotemporal spikes (also known as benign partial epilepsy of childhood and benign rolandic epilepsy). This syndrome is characterised by infrequent highly characteristic partial seizures with onset between age 3 and 12 years. Affected children are neurologically and intellectually normal. Seizures usually arise in sleep, are simple partial in form, and typically begin in facial and orobuccal areas with clonic movements, speech arrest, drooling and dysarthria, sometimes evolving to unilateral tonic or clonic seizures. Secondary generalisation may occur. Up to 10% of patients will have experienced a prior febrile convulsion and 40% have a family history of epilepsy. While a variety of pathological changes have been reported in patients who otherwise meet criteria for this syndrome, such findings probably suggest the diagnosis should be revised. The EEG reveals focal spikes, most commonly in the central and mid-temporal region. It should be noted that centrotemporal spikes may be seen in healthy children, the vast majority of whom will never develop epilepsy (Verrotti *et al.* 1999). The syndrome is almost invariably benign with seizures disappearing by the late teens. Treatment does not alter the natural history of the disorder and may only be indicated when there are secondarily generalised seizures or frequent daytime seizures. Counselling for families about the benign nature of the disorder is effective in preventing the psychosocial morbidity that may be associated with the diagnosis of epilepsy (Lerman & Kivity, 1975). Variations from the characteristic clinical presentation are associated with a less favourable outcome (Fejerman *et al.* 2000) and have been referred to as atypical 'benign' localisation-related epilepsy.

Childhood epilepsy with occipital paroxysms. A clinical presentation with onset between 1 and 16 years of age comprising partial seizures arising from the occipital lobes associated with occipital epileptiform abnormalities on the EEG. Panayiotopoulos (1999a) has argued that two syndromes should be distinguished within this group. Early-onset benign childhood occipital epilepsy is a common childhood epilepsy with peak age of onset of about 5 years. It is a benign disorder and seizures are very infrequent; one-third of children have a single seizure only and the median number of seizures is two or three. The characteristic semiology is that of a complex partial seizure featuring eye deviation and vomiting progressing to a unilateral or generalised convulsion. In contrast, late childhood epilepsy with occipital paroxysms is a rare disorder with mean age at onset of around 8 years. Seizures are frequent and characteristically diurnal. A variety of visual phenomena dominate the semiology. Elementary visual hallucinations may be the principal feature early on but the semiology may evolve to include ictal blindness, complex hallucinations, illusions, ocular pain as well

as oculomotor features including eye deviation and eyelid fluttering. A postictal headache closely resembling migraine is common. Seizures often resolve by the late teens but up to 40% of patients may have ongoing occipital lobe seizures requiring treatment.

Reading epilepsy. This is an uncommon syndrome characterised by seizures precipitated by reading either silently or aloud (Koutroumanidis *et al.* 1998; Ramani 1998) (see also discussion of seizures with specific modes of precipitation, later in chapter). Other language-related activities (e.g. writing, mental calculations, reading music) may sometimes trigger seizures and the term *language-related epilepsy* has been suggested. Onset is typically postpubertal but may be as young as 10. Males are affected twice as commonly as females. A family history of similar seizures is found in up to one-quarter of patients. Consciousness is apparently preserved during the seizures, although patients may report subjective impairments of concentration such as mental blocking or getting stuck on a word. The characteristic form of seizure in most patients is myoclonic-like jerking of the jaw and tongue. This may spread to the upper limbs and a secondarily generalised seizure is likely if the patient persists with reading after seizure onset. Less commonly, the seizures are more clearly partial in form, involving paroxysms of alexia without motor features. The classification of the syndrome poses difficulties: in a few patients the seizures are clearly partial with localised unilateral onset, but in the majority the seizures are myoclonic with ictal EEG recordings demonstrating distributed discharges with a left anterior predominance. Using functional MRI to localise spike discharges, Archer *et al.* (2003) have postulated that spikes originating in working memory areas of the dorsolateral prefrontal cortex spread to activate a cortical–subcortical circuit.

Symptomatic and cryptogenic localisation-related epilepsy

The syndrome of *epilepsia partialis continua* of childhood (Kojewnikoff's syndrome) is given special status in the current classification syndrome. *Epilepsia partialis continua* (EPC) is defined as continuous clonic muscular twitching lasting for hours, days or even longer. Thus it is a form of partial status epilepticus involving protracted simple partial motor seizures. A review of 36 patients presenting with this clinical picture revealed two who had myoclonus of subcortical origin and recommended that such cases be termed 'myoclonia continua', reserving the label of EPC for continuous muscle jerks of cortical origin (Cockerell *et al.* 1996; Placidi *et al.* 2001). The ictal EEG may show focal epileptiform discharges or slowing, but is often normal. Causes include structural lesions such as cerebrovascular disease, tumours and trauma but in up to half of patients structural imaging is normal. Metabolic disturbances, including hyperglycaemia, hyponatraemia and hepatic encephalopathy,

may also present with EPC (Schomer 1993). In children, the term Kojewnikoff's syndrome is associated with two different clinical pictures: (i) recurrent infrequent episodes of EPC without any underlying progressive neurological disorder; and (ii) EPC occurring in the context of a variety of progressive disorders. In the latter group, the most important association is with Rasmussen's encephalitis, a rare immune-mediated encephalitis of unknown aetiology that leads to progressive cerebral hemiatrophy and associated neurological dysfunction (Bien *et al.* 2005). In this condition the localisation of focal motor seizures migrates as the disease progresses. Other disorders associated with EPC include inborn errors of metabolism and infective and paraneoplastic encephalitis.

Anatomically localised syndromes

The 1998 ILAE classification proposal also described four anatomically defined localisation-related syndromes: temporal, frontal, parietal and occipital lobe epilepsies. These syndromes are thus set apart from the remainder of the classification system which is based on aetiology. However, they are of the utmost importance in clinical practice as they account for at least two-thirds of adults with epilepsy. The clinical features of these syndromes are therefore considered in detail later in Anatomically defined epilepsy syndromes.

Generalised epilepsy

Idiopathic generalised epilepsy

Three of the idiopathic generalised epilepsy syndromes occur in the neonatal period or infancy and are not considered further here. The remaining syndromes are childhood and juvenile absence epilepsy, juvenile myoclonic epilepsy and epilepsy with generalised tonic–clonic seizures on awakening (Duncan 1997a; Janz 1997; Andermann & Berkovic 2001). Diagnosis at syndrome level has critical implications for choice of treatment and for the likelihood of remission. However, there is considerable overlap between these syndromes and they may best be viewed as part of a continuum. Typical absence seizures that begin before the age of 8 have a good chance of remitting by early adulthood. With later onset, absences are more likely to be associated with other seizure types and the prognosis becomes less favourable. At the opposite end of the continuum, when onset occurs later in childhood, the predominant seizure types are likely to be myoclonic or tonic–clonic (usually seen on awakening). In this group, the response to medication, specifically valproate, is excellent but there is an extremely high chance of relapse if treatment is withdrawn.

Childhood absence epilepsy is characterised by the appearance of absence seizures in early childhood, typically between the ages of 4 and 8. The annual incidence is 6–8 per 100 000. There is a slight female preponderance and a strong genetic predisposition: a twin study found concordance rates in monozygotic and dizygotic twin pairs of 75% and 5%, respectively,

(Gedda & Tatarelli 1971). Up to 40% of patients will develop generalised tonic–clonic seizures, often 5–10 years after the onset of absences. The disorder is usually benign: neurological and intellectual development is normal, there is an excellent response to medication (over 70% completely remit) and 80% of patients may be withdrawn from medication and remain seizure-free by early adulthood. The ictal EEG is characteristic, showing 3-Hz spike-and-wave discharges. Absence seizures are reliably triggered by hyperventilation, which can easily be performed during EEG recording allowing the diagnosis to be established with certainty. With a later age at onset, there is increased likelihood of atypical features and overlap with other syndromes. Such atypical features include a faster spike-and-wave pattern on EEG, associated myoclonic or tonic–clonic seizures and a greater chance that seizures will not remit. Cognitive and behavioural problems are also more likely in this group.

Juvenile absence epilepsy is arbitrarily defined as absence seizures with onset after the age of 10. It is less common than the childhood form of the disorder but also has a strong genetic predisposition. Up to 80% of patients will develop generalised tonic–clonic seizures and around 15% will develop myoclonic seizures.

Juvenile myoclonic epilepsy (JME) accounts for about 10% of all epilepsy. Up to 50% of patients have a family history of epilepsy with variable patterns of inheritance. Genetic heterogeneity is likely. Males and females are equally affected and the disorder presents in the early teenage years (80% between 12 and 18). Myoclonic jerks are the defining clinical feature and a necessary criterion for the diagnosis. They occur in isolation in less than 5% of patients. Generalised tonic–clonic seizures are seen in 95% and absence seizures in about 40%. When absence seizures occur they usually precede myoclonic seizures by years. Such patients will therefore initially be classified as having absence epilepsy, being reclassified as having JME when myoclonic jerks appear. However, most patients with JME present after their first tonic–clonic seizure. The diagnosis is often missed because many patients do not volunteer a history of myoclonic jerks, which usually precede the first tonic–clonic seizure by months or years. Specific enquiry about shakiness, clumsiness, twitches and ‘nervousness’ is often required to elicit this distinctive history. Sometimes the jerks may only be noticed by the patient’s family. A characteristic feature of the myoclonic and tonic–clonic seizures in JME is that they tend to occur first thing in the morning just after awakening. A cluster of myoclonic jerks may sometimes give the patient a useful warning that a tonic–clonic seizure is impending. Sleep deprivation and alcohol intake the night before are common triggers for seizures. Up to 30% of patients with JME are photosensitive. The interictal EEG shows 4–6 Hz polyspike and slow-wave discharges that last up to 20 seconds. Sleep deprivation is a

useful procedure for increasing the sensitivity of EEG and discharges may be provoked by hyperventilation and photic stimulation. Over 50% of patients have focal EEG abnormalities including asymmetry of generalised discharges, focal slow waves, spikes or sharp waves. Over 80% of patients become seizure-free with valproate monotherapy. Lamotrigine, topiramate and levetiracetam are effective second-line drugs. Carbamazepine and phenytoin typically increase seizure frequency. Lifelong treatment is widely held to be necessary because of a very high relapse rate on treatment withdrawal. The specificity of this treatment response and requirement for lifelong treatment underline the importance of correctly identifying this disorder.

Epilepsy with generalised tonic–clonic seizures on awakening is distinguished from JME either by the absence of myoclonic jerks in a patient with early-morning tonic–clonic seizures (usually defined as occurring within 2 hours of awakening) or when myoclonic seizures make their first appearance some time after tonic–clonic seizures. In practice this distinction may be very difficult to make and there is considerable overlap between the two syndromes in terms of age of onset, seizure precipitants and EEG findings. As with JME, valproate is the treatment of choice (although perhaps with a slightly less favourable outcome) and there is a very high relapse rate if treatment is withdrawn.

Other idiopathic generalised epilepsy syndromes. Typical absence seizures occurring in association with conspicuous eyelid or perioral myoclonus are not currently recognised as discrete syndromes but may have distinct implications for prognosis (Panayiotopoulos 2005). In eyelid myoclonia with absences, brief absences are associated with striking rhythmic jerking of the eyelids, often with jerky upward deviation of the eyes and retropulsion of the head. There is a strong association with photosensitivity. In perioral myoclonia, brief absences are associated with similar myoclonic jerking involving the perioral facial and masticatory muscles. There is no association with photosensitivity (see below). In both conditions, there may be a poor response to treatment and perioral myoclonia with absences is associated with a high incidence of absence status.

Syndromes characterised by seizures with specific modes of precipitation

Reflex seizures. The old term ‘reflex seizures’ is still widely used to denote seizures that occur in response to some specific precipitating stimulus. The current classification system includes categories for both localisation-related and generalised syndromes characterised by such seizures. Visual stimuli are the most frequent trigger for reflex seizures (Ferlazzo *et al.* 2005). Flickering light, as encountered with sunlight through trees, disco lighting, television and video games, is the most common visual trigger but pattern sensit-

ivity, typically related to strongly lined patterns such as escalator steps, is also seen. Seizures are usually generalised, although photosensitive partial seizures in patients with and without occipital lesions have been described. Pure photosensitive epilepsy, in which seizures occur exclusively in response to visual stimulation, accounts for some 40% of cases. Most of the remaining 60% will have idiopathic generalised epilepsy, especially JME in which photosensitivity is seen in 40–90%. Photosensitivity is seen in up to 10% of epilepsy arising in late childhood. It is more common in females. EEG recording usually reveals a prolonged spike (or polyspike)-and-wave photoparoxysmal response (PPS) to intermittent photic stimulation (typically 10–30 flashes per second). Photosensitivity is inherited, either as an autosomal dominant trait with incomplete penetrance or through multiple susceptibility genes. Up to 50% of healthy siblings of patients with photosensitive epilepsy will demonstrate PPS. The antiepileptic of first choice is valproate, but preventive measures may be very helpful. Avoiding the stimulus by covering one eye and wearing polarised or tinted glasses may be effective. Television sets with high refresh rates (100 Hz as opposed to 50 Hz) are less likely to trigger photosensitivity. Cognitive tasks, both verbal (reading epilepsy) and non-verbal, are probably the next most frequent stimuli to be associated with reflex seizures. Reading epilepsy (Koutroumanidis *et al.* 1998; Ramani 1998) is currently classified as a localisation-related syndrome but a proportion of patients have generalised epilepsy, as evidenced by seizure semiology and EEG findings, including the presence of PPS in some 9%. Non-verbal tasks, such as mental calculation and spatial tasks, are also associated with reflex generalised seizures (Goossens *et al.* 1990). Reflex partial seizures have been described with a wide variety of triggers. Somatosensory stimulation and sudden voluntary movement of the limbs may in rare cases trigger partial seizures in patients with cerebral lesions. Musicogenic seizures usually have a temporal lobe lesional basis (Zifkin & Zatorre 1998). Other examples include eating, proprioceptive stimuli and hot water. The chief importance of reflex epilepsy for the psychiatrist is that attacks may easily be suspected of being functional in origin until their reflex epileptic basis is recognised. The existence of such clear-cut examples is also a reminder of the importance of searching for possible precipitating factors in other patients.

Self-induced seizures. Patients with reflex epilepsy may induce seizures by deliberately exposing themselves to triggering stimuli (Ng 2002). Over 90% of such cases involve children with photosensitive epilepsy who pass their hand repeatedly in front of their eyes, blink rapidly, stare at a television from a short distance, or jump up and down in front of venetian blinds. A more recently recognised triggering manoeuvre involves extreme upward deviation of the eyes with slow eyelid closure. Self-induced seizures are notoriously diffi-

cult to treat. Some children appear to derive pleasure from self-induction; in others it may represent a form of compulsion or a wilful means of gaining attention or avoiding stress.

Cryptogenic or symptomatic generalised syndromes

This category includes a number of clinical syndromes in which generalised seizures are associated with profound intellectual impairment. In many cases an underlying cause can be identified. In others, however, the aetiology remains unknown; a proportion of these may represent as yet unidentified genetic syndromes and thus might better be regarded as 'idiopathic'. The syndromes are described in order of their age of onset.

West syndrome consists of the triad of infantile spasms, arrest of psychomotor development and the characteristic EEG finding of hypsarrhythmia. The latter consists of almost continuously abnormal electrical activity, with irregularly recurring spikes and slow waves of high amplitude in all leads. The typical spasms consist of brief repeated flexor, or more rarely extensor, spasms of the trunk and limbs. 'Salaam attacks', with bowing of the head and trunk, are a common but not constant manifestation. Spasms may be asymmetrical and there may be associated partial seizures. The onset peaks at 4–7 months of age and almost all cases present during the first year of life. Boys are affected more often than girls. In the great majority of cases an underlying cause can be identified (birth hypoxia, the presence of cerebral malformations or metabolic disorders) and developmental abnormality has been obvious since birth (symptomatic group). With modern neuroimaging the proportion of patients in whom no cause is found has fallen as low as 10%. The term 'idiopathic West syndrome' is sometimes reserved for the very small proportion of patients who recover spontaneously after a brief period of infantile spasms. In this group, spasms set in after normal development and no aetiology is discovered. For the majority of symptomatic cases, however, the prognosis is grave. Although the spasms rarely persist beyond 3 years of age, other seizures supervene in some 50% of children, particularly in the form of Lennox–Gastaut syndrome (see below). Learning difficulties are observed in up to 85% of cases (Aicardi 1986). Controlling seizures and suppressing EEG abnormalities, both of which interfere with normal function and development, are the main focus of treatment. Conventional antiepileptic treatment is usually without effect. Adrenocorticotrophic hormone (ACTH) or steroids can be successful in suppressing the spasms and the EEG abnormalities. Vigabatrin may be helpful but clear guidelines for its use are still required, especially in view of the potential for retinal toxicity associated with this drug (Hrachovy & Frost 2003).

Lennox–Gastaut syndrome (Markand 2003). Like the above, this is an age-related epileptic encephalopathy of varied

aetiology. The onset is typically between 1 and 8 years of age, mainly in preschool children. The syndrome is characterised by multiple seizure types, intellectual failure and/or behavioural disturbance and by EEG abnormalities comprising diffuse slow spike-and-wave discharges set against an abnormal background with paroxysms of fast 10–12 Hz rhythms that may be associated with a tonic seizure. In one-third of patients, no aetiology is identified and these cases are referred to as cryptogenic Lennox–Gastaut syndrome. The causes identified in the symptomatic cases are diverse and similar to those found in West syndrome. Indeed, in many symptomatic cases the syndrome represents a progression from West syndrome, in which case infantile spasms are either gradually replaced by tonic and other seizure types or there is a seizure-free period with improvement in psychomotor function brought to a halt by the onset of Lennox–Gastaut syndrome. The seizures in Lennox–Gastaut syndrome are frequent, severe and hard to control, consisting of mixed seizure types: tonic attacks occurring particularly during sleep and affecting the axial musculature, atonic and myoclonic attacks and atypical absences. Episodes of non-convulsive status are frequent. In consequence, much of the child's waking life may be spent in an obtunded state. The seizures commonly persist into adult life, and less than 10% of cases make a full recovery. Continuing intellectual impairment is common. As with West syndrome, cases in which no aetiology is found have a better prognosis. Valproate and benzodiazepines have been the mainstay of treatment but more recently introduced drugs, particularly lamotrigine and topiramate, now have a recognised role in treatment as they have established efficacy and a good safety profile. ACTH, prednisolone, ketogenic diet and vagal nerve stimulation (VNS) may also be of benefit (Lee & Ong 2004). Corpus callosotomy is an effective treatment for atonic seizures, which may be very frequent and extremely disabling, but VNS is being evaluated as an alternative surgical procedure (Frost *et al.* 2001).

Epilepsy with myoclonic astatic seizures (Guerrini & Aicardi 2003). This syndrome arises in early childhood (from 7 months to 8 years), usually in a child who has previously developed normally. Up to 80% of patients are boys. There is a strong genetic component with a family history of epilepsy in up to one-third of affected children. Evidence for other aetiologies is usually not found. Thus, the syndrome may be better classified as idiopathic. Onset is typically with tonic-clonic seizures, which may be febrile. Other seizure types appear over time and include myoclonus, atonic seizures, atypical absence seizures, nocturnal tonic seizures and episodes of non-convulsive status. Prognosis is variable, with seizures disappearing completely after 2 or 3 years in two-thirds of patients in whom intellectual functioning may be normal. Outcome seems to be strongly related to seizure

control and a poor prognosis is predicted by the occurrence of episodes of non-convulsive status.

Epilepsy with myoclonic absences (Bureau & Tassinari 2005). This is a rare disorder of middle childhood with a mean age at onset of 7 years. Boys are more commonly affected. The defining characteristics of the syndrome are absence seizures that are associated with dramatic bilateral myoclonic jerks which can be demonstrated to be synchronous with a 3-Hz ictal EEG discharge. Intellectual development is abnormal in approximately 50%. Aetiology can be identified in one-third of patients, including perinatal insult and karyotypic abnormalities. Additional seizure types including absence and tonic-clonic seizures are seen in 40% of patients. Frequent tonic-clonic seizures predict a poor response to treatment and poor long-term prognosis.

Epilepsy syndromes undetermined whether focal or generalised

This group of disorders includes syndromes in which both generalised and partial seizures occur and in which underlying aetiology is poorly understood. Certain neonatal syndromes are included in this category and are considered only briefly.

Severe myoclonic epilepsy in infancy (Dravet's syndrome) is a progressive epileptic encephalopathy that develops in the first year of life after a short period of normal development. Initial seizures are usually febrile convulsions but mixed seizure types soon appear. Associations with mutations in the sodium channel gene *SCN1A* have recently been described (Guerrini & Aicardi 2003).

Epilepsy with continuous spike-waves in slow-wave sleep describes syndromes characterised by specific cognitive deficits associated with almost continuous high-frequency spike-and-wave discharges during slow-wave sleep. The most common presentation is better known as Landau–Kleffner syndrome (acquired epileptic aphasia), a rare childhood disorder that may present with either seizures or aphasia. Patients with *acquired epileptic opercular syndrome* present with progressive loss of voluntary movement of the mouth including kissing, oral expression and eating, often associated with drooling. There is overlap between presentations and some regard Landau–Kleffner syndrome and epilepsy with continuous spike-waves in slow-wave sleep as the same condition (Shafrir & Pinsky 1995). Onset is usually before the age of 5 years. The child loses comprehension of speech after seemingly normal development, and rapidly ceases to use speech to communicate. The cognitive deficits may sometimes extend beyond auditory comprehension, and behaviour disorder with agitation, echopraxia and frontal characteristics may develop. Seizures are usually

mild and infrequent, and may be partial motor or tonic-clonic in form. In some 20% of cases of Landau-Kleffner syndrome, obvious seizures remain in abeyance, although close inspection may reveal minor episodes. The striking EEG abnormality is the presence of almost continuous spike-and-wave discharges during slow-wave sleep, which may be relatively localised to bilateral rolandic areas in the opercular variant of the syndrome. The EEG during wakefulness shows spikes or spike-and-wave complexes, usually generalised or multifocal bilaterally in the temporal and parietal regions. The seizures are typically resistant to treatment but usually remit before the age of 15 years. Language difficulties may persist even into adult life. The surgical procedure of multiple subpial transection is effective in controlling seizures and improving the EEG and may be associated with dramatic improvements in language function (Selway & Dardis 2004). Further research is required to define more clearly the indications for this approach. The cause of the condition is unknown, although symptomatic cases with acquired lesions or neurodevelopmental abnormalities have been reported.

Special syndromes: situation-related seizures

The current classification system lists a number of situation-related syndromes; disorders in which isolated or recurrent seizures occur in the presence of an identifiable triggering event. Childhood febrile convulsions are included in this category, as are seizures arising as a consequence of an acute metabolic or toxic event (see Causes of acute symptomatic seizures). Febrile convulsions are of considerable significance because they are common and because of their association with epilepsy in later life.

Febrile convulsions are seizures occurring in childhood in association with a febrile illness not caused by a CNS infection (Waruiru & Appleton 2004; Sadleir & Scheffer 2007). They are the most common form of epilepsy, affecting 2–5% of children. Most febrile convulsions start in the second year of life, with a range from 2 months to 7 years. Approximately one-third of children will experience a second episode, usually within 3 years of the first. The risk of a recurrent febrile convulsion is increased if the first seizure occurs before 18 months of age, if there is a family history of febrile convulsions, or if the first seizure occurred early in the course of a febrile illness or with a relatively low fever. Most febrile seizures are generalised and of short duration (90% under 10 minutes). Overall, 2–4% of children will experience at least one unprovoked seizure following a single febrile convulsion, a risk up to four times that in the general population. This modestly increased risk for later epilepsy applies to both generalised and localisation-related epilepsy (Trinka *et al.* 2002). An increased risk of epilepsy following febrile convulsions has most consistently been associated with a family history of epilepsy, the presence of early-onset

neurodevelopmental abnormalities and ‘complex’ features present during the febrile convulsion. These complex features are prolonged duration (greater than 10–15 minutes), recurrent febrile seizures within a single febrile illness and the presence of focal neurological features during or after the seizure. Annegers *et al.* (1987) found that the risk of unprovoked seizures rose from 2.4% following a ‘simple’ febrile convulsion to 6–8% for those with a single complex feature, 17–22% with two complex features and 49% with all three complex features. There is a rapidly expanding literature on the genetics of febrile convulsions. Between 25% and 40% of patients have a family history of febrile convulsions. Polygenic inheritance most likely contributes to the majority of cases, but a small number of families inherit the disorder as an autosomal dominant condition, and a number of genes have recently been identified (Audenaert *et al.* 2006). The controversial relationship between febrile convulsions, hippocampal sclerosis and temporal lobe epilepsy is discussed under Aetiology of temporal lobe epilepsy.

Anatomically defined localisation-related epilepsy syndromes

Seizures originating in different anatomical locations take characteristic forms but there is considerable overlap. The symptoms at the very beginning of a seizure generally provide the most critical clue to localisation, but a focal epileptic discharge may spread to adjacent brain regions so rapidly (within milliseconds) that the clinical manifestations of seizures arising in functionally quite distinct cortical regions become indistinguishable. Nevertheless, typical modes of presentation that correspond to anatomical location are now recognised and are of considerable importance in clinical practice. Skilled appraisal of clinical semiology will help determine which hemisphere and which cortical region are involved. With respect to aetiology, the syndromes have more in common than otherwise. In the following section the primary aim is therefore to describe the semiological features of each syndrome. Aetiological factors, where distinctive, are mentioned but are dealt with in greater detail elsewhere in the chapter.

Temporal lobe epilepsy

Temporal lobe epilepsy (TLE) is the most common of the anatomically defined syndromes, accounting for around 60% of all patients with localisation-related epilepsy. Temporal lobe seizures produce the most varied and complex auras of all. They are of particular interest to the psychiatrist because they often contain elements that echo symptoms seen in psychiatric disorder.

The most frequent cause of TLE is hippocampal sclerosis, also known as mesial temporal sclerosis or Ammon’s horn sclerosis, accounting for 50–70% of cases in temporal lobectomy series (Bruton 1988). Hippocampal sclerosis is strongly associated with a history of childhood febrile convulsions

Table 6.3 Auras of partial seizures.

Symptom	Frequency in TLE* (%)	Specificity: the relative frequency of aura by localisation syndrome			
		Temporal	Frontal	Parietal	Occipital
Epigastric aura	30–53	+++	–	–	–
Cephalic aura	23–30	++	++	–	–
Anxiety/fear	14–24	++	+	–	–
<i>Hallucinations/illusions</i>					
Visual	16–18	+	–	+	+++
Elementary	5–7	+	–	+	+++
Complex	3	++	–	++	–
Auditory	8–16	+++	–	+	–
Elementary	1–12	+++	–	–	–
Complex	3–4	+++	–	–	–
Olfactory	8–12	+++	+	–	–
Gustatory	3–11	+++	+	–	–
Somatosensory	2–19	+	++	+++	–
Dysmnestic/déjà vu	7–18	+++	–	–	–
No aura	10–51				

–, uncommon (though may occur)/not a specific feature for that localisation, ranging to +++, relatively common and/or specific.

* Figures for the prevalence of these symptoms in temporal lobe epilepsy (TLE) are derived from series reported by Currie *et al.* (1971), King and Ajmone Marsan (1977), Taylor and Lochery (1987) and Palmmini and Gloor (1992). Estimates of the relative frequency in different lobar epilepsies are derived from King and Ajmone Marsan (1977) and Palmmini and Gloor (1992).

but the causal direction of this association has not been established: hippocampal sclerosis may be the pathological signature of severe febrile convulsions or there may be underlying disorders that predispose to both febrile convulsions and TLE (see Aetiology of temporal lobe epilepsy). Other causes of TLE include dysembryoplastic neuroepithelial tumours, cavernous angiomas, gliomas, cortical dysplasia and gliosis secondary to encephalitis or meningitis.

Temporal lobe seizures may take the form of simple and complex partial seizures, with both occurring in some 70% of patients (Janszky *et al.* 2004a). Compared with extratemporal seizures, those arising in the temporal lobes characteristically have a gradual onset, usually feature a conspicuous motionless stare and are relatively prolonged, with automatisms often continuing for 2 minutes, occasionally even longer. A wide variety of auras occur in TLE and many are highly characteristic (Table 6.3).

Auras of temporal lobe epilepsy. A variety of autonomic features and visceral sensations figure prominently in temporal lobe auras. The epigastric aura is the most common, being reported by up to 50% of patients with TLE (Henkel *et al.* 2002). It consists of ill-defined sensations rising from the epigastrium towards the throat, typically described as churning, ‘butterflies’ or a feeling of nervousness. Also frequent are inexplicable odd sensations in the head (cephalic aura), although these have less specificity for TLE. Other autonomic effects include changes in skin colour, blood pressure,

heart rate, perspiration, salivation and piloerection. Subjective dizziness is common. True vertigo accompanied by tinnitus and changes in auditory perception is rare.

Affective experiences are a feature of approximately one-quarter of temporal lobe auras. The most common is anxiety, which is often intense (ictal fear) and wells up suddenly without provocation. Other unpleasant affects include depression, guilt and, rarely, anger. Pleasurable affects of joy, elation or ecstasy occur less frequently (Stefan *et al.* 2004). Ictal emotional experiences may be very intense and tend to have a unique, though often difficult-to-describe, quality that makes them unlike anything else in the patient’s experience: they are usually stereotyped and crude, lacking the subtlety of normal emotions. Affective auras are an intrinsic part of the seizure, and not merely a reaction to some other aspect of the aura. The emotional content of the aura may nevertheless colour hallucinatory experiences or occasionally be associated with disturbed behaviour. Biraben *et al.* (2001) have drawn attention to the behavioural features that accompany intense ictal fear, which may include a call for help, marked agitation or frightened immobility. These authors and others have described an association between ictal fear and non-dominant medial temporal foci (Hermann *et al.* 1992; Sazgar *et al.* 2003).

Biraben *et al.* (2001) report a detailed investigation of eight patients with ictal fear. All but one were fully conscious throughout their seizures and the remaining patient had only questionable and momen-

tary impairment. Despite preserved awareness, clear oro-alimentary automatisms (lip-smacking, chewing, swallowing) were seen in all but one patient and dystonic posturing or fleeting localised clonic movement were almost as common. The patients were thoroughly investigated with ictal EEG, including depth recordings, MRI and single-photon emission computed tomography (SPECT). In seven cases the epileptogenic lesion was in the temporal lobe (three on the left, three on the right and one bilateral; six involved the non-dominant hemisphere); the remaining patient had a frontal lobe focus. Seizure onset in medial temporal lobe structures was associated with mild subjective mood changes only. As the emotional experience escalated to one of fear accompanied by autonomic and behavioural features, there was an associated spread of EEG abnormalities to frontal regions. The authors propose that the syndrome of intense ictal fear is associated with functional involvement of a distributed limbic network involving medial temporal lobe, orbito-prefrontal cortex and anterior cingulate.

Cognitive abnormalities include disturbances of speech, memory and thought. Vocalisation is seen in approximately 50% of temporal lobe seizures. It is usually non-verbal, in which case it may be associated with either dominant or non-dominant foci and has no lateralising value. However, speech automatisms (recurrent, irrelevant or emotionally toned utterances), which can be thought of as evidence of preserved speech during the seizure discharge, are strongly related to a non-dominant temporal lobe focus (Williamson *et al.* 1998). Disturbances of memory (*dysmnestic aura*) range from sudden difficulty with recall to compulsive reminiscence on topics, scenes or events from the past. The essential quality of recognition may change, with strong feelings of familiarity or unfamiliarity leading to *déjà vu* and *jamais vu*. *Presience* is a related phenomenon in which patients describe a profound sense of 'knowing' what is about to happen (Sadler & Rahey 2004). In the rare panoramic memory, the patient feels that whole episodes from his past life are lived again in a brief period of time as complex organised experiences. Indeed, distortion of time sense is often an integral part of the experience of the aura, time appearing to rush by precipitately or alternatively to stand quite still.

The purely subjective disorders of thinking constitute some of the most striking auras. They are rare and have less specificity for TLE, having also been described in frontal lobe seizures (Mendez *et al.* 1996). Patients may become abruptly aware of difficulty in thinking coherently, of mixing things up, or of great confusion and turmoil in their mind. There may be a compulsion to think on certain restricted topics (forced thinking), or there may be intrusion of thoughts or of stereotyped words or phrases against the subject's will (evocation of thoughts). A sudden cessation in the stream of thought may occur and later be described in a manner indistinguishable from schizophrenic 'blocking'.

Altered perceptual experiences include both distortions of real perceptions (illusions) and spontaneous hallucinations.

Hallucinations of taste (gustatory) and smell (olfactory) derive from medial temporal lobe structures, particularly the amygdala, and are of considerable significance for the diagnosis of TLE (Acharya *et al.* 1998). They are nevertheless uncommon, accounting for less than 10% of temporal lobe auras, and may also be seen in frontal lobe seizures. The smells and tastes are usually described as unpleasant. Tumours are the most common aetiology associated with olfactory auras (Acharya *et al.* 1998). Sounds may seem suddenly remote or intensely loud. Auditory hallucinations, associated with foci in the superior lateral temporal gyrus, may be simple or complex, ranging from ringing and buzzing noises to organised experiences such as music or voices. Visual illusions may include objects appearing larger (macropsia) or smaller (micropsia), inclined at an angle (plagiopsia), elongated or flattened (dysplaptsia), drained of colour (achromatopsia) or infused with a specific colour (erythropsia, red; xanthopsia, blue). There may be distorted perception of distance, objects may be seen in multiples (monocular diplopia, polyopia), or there may be image persistence or perseveration in the form of an after-image (palipopsia). Visual hallucinations may consist of the simple elements described for occipital seizures, but more characteristically involve complex formed hallucinations of scenes, faces or visions of past experiences. Hallucinations that appear to involve some replay of memory clearly overlap with dysmnestic phenomena and indeed such aura are often associated with *déjà vu* phenomena and an odd 'dreamy state' (Vignal *et al.* 2007). It is therefore not surprising that complex visual hallucinations have been described with both medial temporal lobe foci (Bien *et al.* 2000; Vignal *et al.* 2007) and lateral temporal lobe foci (Wieser 2000). Negative visual symptoms are more typical of occipital lobe epilepsy but are sometimes seen in TLE, and a concentric constriction of the visual field (tunnel vision) may be specific for temporal lobe aura (Bien *et al.* 2000). The emotional quality of perceptual experiences may change, so that objects, sounds or events suddenly acquire a peculiar and vivid significance. The patient may alternatively feel suddenly remote from the environment, and feelings of derealisation and depersonalisation may be marked.

These varied aspects of the auras can occur in any combination. There is often a characteristic 'march', passing for example from an initial epigastric sensation to gustatory hallucinations to forced thinking, or from intense *déjà vu* to an overwhelming sense of fear. Sometimes various aspects of the aura appear to occur simultaneously, or the content is so rich and strange that the patient lacks the vocabulary to describe the experiences. Many are extremely bizarre, particularly those which involve disturbance of appreciation of reality and of the self. Williams (1966) pointed out that the temporal lobes perform the function of integrating sensations of all kinds, and in addition probably contain the neural substrates for emotion itself:

It is the integration of the whole of exteroceptive and proprioceptive sensations with emotions and moods which culminates in the ultimate sense of 'I am', so that it is not at all surprising that disintegration of this organisation, with retention of sensation, leads to so many of the bizarre disturbances of self which disturb the patient with temporal lobe epilepsy.

The precise content of the auras may sometimes change with the passage of time, and scrutiny of the patient's notes may reveal well-documented phenomena earlier in the illness of which the patient now has no recollection. This tendency can sometimes increase the risk of the patient being regarded as suffering from a psychogenic disorder.

Ictal semiology and automatisms in TLE. The motor manifestations of TLE have often been overlooked yet they are common and in some instances provide reliable lateralising signs. Dystonic posturing, most commonly of the hand or arm, occurs in up to 70% of temporal lobe seizures and strongly suggests a contralateral focus. Versive movements of the head, eyes and even trunk are also common. At seizure onset they are perhaps associated with an ipsilateral focus (Williamson *et al.* 1998). A more reliable lateralising sign is versive movement occurring late in the seizure, immediately prior to secondary generalisation, at which point it is strongly associated with a contralateral focus (head, eyes and/or trunk turn away from the side of seizure origin) (Marks & Laxer 1998; Williamson *et al.* 1998). Unilateral clonic movements also indicate a contralateral focus but are less common.

The most frequent automatisms are oro-alimentary (lip-smacking, chewing, swallowing) and gestural (fumbling, picking, rubbing movements). Unilateral gestural automatisms are suggestive of an ipsilateral focus, probably because of ictal paresis of the contralateral limb. Other common automatisms include ictal speech, grimacing, wandering and searching behaviour. Automatisms involving the lower limbs in pedalling or kicking movements are rare in TLE and more often associated with frontal lobe seizures. The prolonged nature of automatisms in TLE has already been mentioned. Slow gradual recovery with postictal delirium extending over several minutes is characteristic and headache is common. Postictal dysphasia suggests a focus in the dominant hemisphere but care must be taken to distinguish this from non-specific aspects of impaired communication associated with delirium. Postictal nose-rubbing is common and is ipsilateral to the seizure focus in 90% of cases (Geyer *et al.* 1999). Todd's paresis is rare in TLE but lateralises seizure onset to the contralateral hemisphere. Patients are usually amnesic for the ictal period covering the blank stare and automatisms. Secondary generalisation is less common than with extratemporal partial seizures.

The clinical features that are most helpful in lateralising temporal lobe seizures are summarised in Table 6.4. Seizures arising in the lateral neocortical temporal lobe are more likely

Table 6.4 Clinical features of temporal lobe seizures with lateralising value.

Lateralising value	Semiological feature
Ipsilateral	Unilateral gestural automatisms Postictal nose rubbing
Contralateral	Dystonic posturing Late versive movement (preceding secondary generalisation) Unilateral clonic activity (uncommon) Todd's paresis (uncommon)
Dominant hemisphere	Postictal dysphasia
Non-dominant hemisphere	Ictal speech

Note that the aura of temporal lobe epilepsy have little lateralising value with the possible exception of ictal fear, which may suggest a focus in the non-dominant hemisphere.

to feature complex auditory and visual aura with relatively prolonged preservation of awareness at seizure onset. Motor phenomena are also more common with foci in this area (Wieser 2000).

Frontal lobe epilepsy

Frontal lobe epilepsy (FLE) probably accounts for 20–30% of localisation-related epilepsy (Manford *et al.* 1992; Jallon *et al.* 2001). Post-traumatic aetiology is common, although tumours and cortical dysplasia are more frequent in surgical series (Manford *et al.* 1996a). *Autosomal dominant nocturnal frontal lobe epilepsy* is a rare but distinctive disorder characterised by autosomal dominant inheritance with high penetrance and frequent nocturnal frontal seizures with complex hyperkinetic behavioural automatisms (Scheffer *et al.* 1995). Mutations in the neuronal nicotinic acetylcholine receptor α_4 and β_2 subunits have been identified (Phillips *et al.* 2001) (see Genetic basis of epilepsy, later in chapter). After TLE, patients with FLE are the second largest group to receive surgical treatment for epilepsy. With improvements in neuroimaging and depth EEG techniques, the proportion of operable FLE seems likely to increase. Considerable effort has therefore been devoted to more precisely defining the semiology of frontal lobe seizures. Overall, frontal lobe seizures tend to begin and end abruptly, are brief (usually less than 1 minute in duration), often frequent, and show a tendency to occur at night and in clusters. Motor phenomena, which may include complex posturing and behavioural automatisms, are usually the most conspicuous feature. A number of syndromes corresponding to anatomical localisation within the frontal lobe have now been delineated (Williamson & Jobst 2000; McGonigal & Chauvel 2004). Some, such as simple partial motor seizures of the Jacksonian type, are relatively common, well recognised and present few diagnostic difficulties. Other presentations have been described relatively

recently and still remain unfamiliar to those not working in the field of epilepsy. These syndromes are of particular importance to psychiatrists as their bizarre nature means they are often mistaken for non-epileptic dissociative seizures. The anatomical classification of these syndromes is approximate and there is considerable overlap between them (Manford *et al.* 1996a).

Focal clonic motor seizures clearly implicate involvement of the contralateral primary motor cortex in the pre-rolandic gyrus. They may occasionally be seen in association with seizure discharges spreading to this region from elsewhere in the frontal lobe. Focal motor seizures may occur as a special form of status epilepticus (*epilepsia partialis continua*), in which case the underlying pathology may be focal, diffuse (e.g. Rasmussen's encephalitis) or be associated with metabolic disturbance.

Unlike other frontal lobe seizures, those arising in the supplementary motor area (SMA) are sometimes preceded by an aura that is usually somatosensory (Morris *et al.* 1988). The sensations are vague, distributed and less well defined compared with those associated with parietal foci. More often, SMA seizures begin with the abrupt onset of complex motor postures usually involving the upper limbs. The 'fencing posture', in which the contralateral arm is raised above the head and flexed at the elbow, is the classic example. Versive movements of the eyes and head are also common and, as described above for TLE, when they occur late in the seizure prior to secondary generalisation they lateralise seizure onset to the contralateral hemisphere. Postures are typically bilateral and may evolve to writhing twisting movements. Consciousness is usually preserved throughout the seizure. Another rare form of dorsolateral frontal seizure is the so-called 'frontal absence', which consists of behavioural arrest accompanied by spike-and-wave rather than tonic discharge on EEG.

The most bizarre frontal lobe seizures are those involving complex behavioural automatisms. The anatomical localisation within the frontal lobes is less certain for these seizures but current evidence suggests that prefrontal origin, perhaps especially from the orbitomedial cortex, is likely (Williamson *et al.* 1985; Waterman *et al.* 1987; So *et al.* 1998; Jobst *et al.* 2000; Kotagal *et al.* 2003). These must surely rank as some of the most dramatic presentations in neurology. They are often referred to as *hypermotor seizures*, a term that usefully evokes the core features. Seizures begin very abruptly. There is often intense grimacing, with the patient seemingly gripped by some overwhelming emotion. Typically, however, patients do not describe ictal fear. Complex behavioural automatisms then follow. These are typically frantic, bilateral and often overtly sexual. Pedalling, thrashing, kicking movements are common and may be of such a degree that patient appear to thrust themselves out of bed. The upper limbs may be involved in vigorous clapping, finger-clicking, grasping, rubbing and pounding move-

ments. Sexual automatisms often appear aggressive and include pelvic thrusting, undressing and genital manipulation. Speech arrest is a feature of dominant hemisphere frontal seizures but speech automatisms accompanying hypermotor seizures arising from the non-dominant hemisphere may also be dramatic, with screaming and swearing. Patients often report partial awareness during these seizures. Brief duration (mean 20–40 seconds) is a characteristic feature and they typically end as abruptly as they begin.

Clearly, there is scope for confusion between frontal lobe seizures and non-epileptic events yet the syndromes have now been so well described that experienced clinicians are often able to make a diagnosis after witnessing a seizure. The bizarre nature of the automatisms, preservation of awareness during bilateral motor involvement and abrupt termination of the seizures are features particularly likely to raise doubts about diagnosis. Diagnostic difficulties are compounded by the fact that interictal and ictal scalp EEG is often normal (Bautista *et al.* 1998). Helpful pointers include the highly stereotyped nature of the attacks, brief duration and, during EEG telemetry, their occurrence during electrographically documented sleep.

Parietal lobe epilepsy

Parietal lobe epilepsy is rare, probably accounting for less than 5% of localisation-related epilepsy (Sveinbjornsdottir & Duncan 1993; Siegel & Williamson 2000). Tumours are the most common aetiology. Somatosensory auras are reported by some 80% of patients, with elementary paraesthesiae by far the most common feature. These may be described as tingling, numbness, prickling, crawling or electrical sensations and implicate the primary somatosensory region in the post-central gyrus. The paraesthesiae are usually contralateral to the epileptic focus but may rarely be bilateral or ipsilateral. Pain, which may be intense, is less common but quite specific for parietal foci, and thermal sensations rarer still. Paraesthesiae may spread in a Jacksonian manner and be accompanied by focal clonic or tonic motor phenomena. Seizures arising on the medial surface from the paracentral lobule may give rise to genital sensations that are usually unilateral and not necessarily described as pleasurable. These tactile sensations are distinct from the orgasmic aura occasionally described in TLE (Janszky *et al.* 2004b) but there may be sexual elements in the ensuing seizure semiology. Foci in posterior regions of the parietal convexity give rise to a variety of complex though uncommon aura. These include distortions of body image, in which parts of the body seem altered in shape or size or even to be absent, illusions that parts of the body are moving or have changed posture, and ictal ideomotor apraxia (ictal paroxysmal paralysis). Panic has been described as a feature but is now more closely associated with TLE. Epileptogenic lesions that lie across the boundaries of the parietal lobe may obviously present with features more characteristic of the adjacent brain region. Similarly, following the aura, ictal

spread is usually rapid and the semiology of automatisms in parietal complex partial seizures is non-specific. In a series of 82 patients with parietal lobe epilepsy, 57% exhibited unilateral clonic activity (suggesting spread to precentral cortex), 28% tonic posturing (suggesting involvement of the SMA) and 17% demonstrated oral or gestural automatisms (compatible with temporal lobe involvement) (Salanova *et al.* 1995).

Occipital lobe epilepsy

Occipital lobe epilepsy accounts for around 5–7% of localisation-related epilepsy but is probably under-recognised (Manford *et al.* 1992; Jallon *et al.* 2001). Childhood syndromes are frequently misdiagnosed as migraine (Panayiotopoulos 1999b) and in adults occipital lobe seizures notoriously mimic other partial seizures because of rapid propagation to temporal and frontal lobes. Elementary visual hallucinations are the hallmark of occipital seizures but are not seen in all cases (Sveinbjornsdottir & Duncan 1993; Blume & Wiebe 2000). The hallucinations consist mainly of bright, coloured spots, circles, balls or blobs. They typically appear in the contralateral hemifield and move, flash or twinkle. Negative phenomena, such as scotoma, ‘black or white outs’, and ictal amaurosis are less common. Complex visual illusions and hallucinations are associated with temporal lobe seizures but may be seen with occipitotemporal foci. Primary occipital motor phenomena include eye deviation, both tonic and oculoclonic, forced eyelid closure and palpebral jerks. In young children, vomiting, pallor and headache are often prominent features. While elementary visual auras are highly characteristic of occipital seizures, the ensuing semiology, like that seen in parietal epilepsy, reflects spread to the temporal and frontal lobes and these features may dominate the clinical presentation leading to false localisation. Postictal blindness may be prolonged and provides an important clue to occipital lobe onset.

Common causes of occipital lobe epilepsy include tumours, trauma and developmental malformations. In a comprehensive review of aetiology in occipital lobe epilepsy, Taylor *et al.* (2003) emphasise the importance of developmental malformations but also highlight certain distinctive syndromes that have specific implications for management. Occipital lobe seizures may be the presenting feature of reversible posterior leucoencephalopathy, seen in acute hypertensive encephalopathy, eclampsia and during immunosuppressant treatment. The characteristic MRI appearance of bilateral T2 signal hyperintensity in occipitoparietal white matter is believed to reflect oedema secondary to disrupted autoregulation of the posterior cerebral circulation. Other clinical features include headache, confusion, vomiting and visual disturbance. It is typically completely reversible with treatment of the underlying cause (Hinchev *et al.* 1996). Another syndrome, epilepsy with bilateral occipital calcifications, is notable because of its association with

coeliac disease. Seizures usually begin in the first decade of life. The typical appearances of bilateral calcification on computed tomography (CT) may not be seen at first presentation and screening for coeliac disease should therefore be considered in all idiopathic cases of occipital lobe epilepsy. A gluten-free diet may have a dramatic effect on seizure control. Occipital seizures are also seen in the progressive myoclonic epilepsies (see Epilepsy occurring in inherited disorders). Finally, three syndromes of idiopathic childhood epilepsy have now been recognised. Early- and late-onset syndromes of childhood epilepsy with occipital spikes are both relatively benign conditions, although the latter not infrequently requires longer-term antiepileptic drug treatment. Idiopathic photosensitive occipital epilepsy presents between 5 and 17 years of age with complex partial seizures (featuring prominent visual aura) triggered by television and videogames. The prognosis is excellent and simple measures taken to avoid triggering factors may make medical treatment unnecessary.

Other syndromes

Other rare forms of epilepsy that can produce puzzling clinical pictures are mentioned briefly.

Gelastic epilepsy. This is a term used for seizures preceded or accompanied by laughter. The laughter may very occasionally be accompanied by a subjective experience of mirth, but is most typically without affect and is of a hollow quality. Some patients report a ‘pressure to laugh’ which is vaguely pleasurable and may be accompanied by lacrimation (*dyscrastic seizure*) (Sturm *et al.* 2000). Gelastic seizures are closely associated with hypothalamic hamartomas, although there are occasional reports of seizures accompanied by laughter in patients with temporal and frontal lobe lesions. The classical view of the syndrome has been that most patients with hypothalamic hamartomas present with gelastic seizures in infancy or early childhood. In such cases, multiple seizure types, both partial and generalised, rapidly supervene and the clinical picture is one of a progressive epileptic encephalopathy with intractable seizures, behavioural disturbance and cognitive decline. However, it is now recognised that some patients, especially those with small hamartomas, may not present until adulthood in which case the clinical picture is distinctly mild and compatible with normal intellect (Mullatti *et al.* 2003). It is thought that the hamartoma is itself epileptogenic, discharges propagating through neighbouring thalamocortical connections to produce generalised seizures, and through limbic pathways to produce partial seizures. Although surgical approaches to the lesion may be difficult, seizures are usually halted following resection of the hamartoma and anecdotal reports suggest cognitive decline may be arrested and behaviour improved (Berkovic *et al.* 2003). Recent evidence from cerebral electrical stimulation studies suggest that gelastic seizures may represent acti-

vation of a hypothetical motor component of laughter in the anterior cingulate cortex, the emotional content of laughter being subserved by temporal regions (Sperli *et al.* 2006).

Transient epileptic amnesia. This distinctive syndrome of recurrent episodes of amnesia has been described relatively recently (Butler 2006). Based on a description of 10 cases and a review of previous reports, Zeman *et al.* (1998) have recommended criteria for the diagnosis: (i) recurrent witnessed episodes of amnesia; (ii) evidence that other cognitive functions are intact during the episodes; and (iii) support for a diagnosis of epilepsy based on EEG findings, the presence of other epileptic semiology and/or a response to antiepileptic drugs. The disorder typically begins in later life. The amnesic episodes are recurrent (average of three per year), characteristically occur on waking, and usually last less than an hour. In 60% of cases there are other clinical features suggestive of TLE, such as olfactory aura or oral automatisms. In the remainder, amnesia is the only ictal manifestation. During the episode the patient displays a dense retrograde amnesia that may extend back in time for days or years. There is usually anterograde amnesia during the episode but the patient may have recall for the episode after recovery, i.e. they may 'remember forgetting'. An intriguing aspect of the syndrome is that it is strongly associated with two specific interictal disturbances of memory, present between episodes of transient amnesia: firstly, accelerated forgetting of newly learned material and, secondly, a characteristic patchy loss of autobiographical memory. Most patients with transient epileptic amnesia spontaneously complain of the latter problem, which involves forgetting emotionally salient episodes (holidays, weddings) from the remote past, events that usually predate the first episode of transient amnesia by many years. Underlying aetiology is typically not identified and the episodes usually resolve completely with antiepileptic medication.

Diencephalic (autonomic) epilepsy is characterised by autonomic symptoms that predominate during attacks. It is likely that most reported examples represent partial seizures arising from the medial temporal lobe. Indeed, the epigastric aura of TLE is regarded, in part at least, as reflecting autonomic dysfunction (Blume *et al.* 2001). Fox *et al.* (1973) reported a patient whose attacks consisted of episodic flushing and sweating, lasting 10–20 minutes, followed by feeling cold and shivering. Slight confusion could sometimes ensue. The rectal temperature fell during attacks and was recorded as low as 34°C. In other cases seizures may take the form of a sudden desire to urinate or defecate, sensations of heat or cold, flushing, hyperpnoea, difficulty with breathing, salivation, lacrimation or abnormal gastric sensations. It may be hard to distinguish such symptoms from those of an anxiety state, although the sudden onset and ending and the regular stereotyped nature of the attacks may give the clue.

Prevalence and aetiology of epilepsy

Prevalence

The prevalence of epilepsy is approximately 7 per 1000 in the developed world (Haerer *et al.* 1986; Keranen *et al.* 1989; Hauser *et al.* 1991). The annual incidence is around 50 per 100 000 and approximately 1 in 30 individuals will develop epilepsy at some point in their lives (Hauser *et al.* 1993; MacDonald *et al.* 2000). Most studies report a slight preponderance of males relative to females, although the difference is rarely statistically significant. Age of onset shows the highest rate in the first year of life and in the elderly, with the lowest incidence in people in their thirties. Epilepsy is more prevalent in areas of lower socioeconomic status (Morgan *et al.* 2000) and a primary-care based study in the south-east of England (Heaney *et al.* 2002) has shown an association between measures of socioeconomic deprivation and the incidence of new cases of epilepsy, suggesting that this relationship is not just a reflection of downward social drift secondary to epilepsy but that factors related to socioeconomic deprivation may be causally related to epilepsy. Of the different types of epilepsy, the great majority appearing in the first 20 years of life are generalised epileptic syndromes, while after this age the proportion of localisation-related epilepsies rapidly increases.

Aetiology

In clinical practice, epilepsy should be viewed as a symptom rather than a disease in itself. A great variety of causes may underlie the occurrence of seizures and need to be carefully investigated. When this is done, however, a considerable number of cases remain in which no cause is discernible. The proportion of such cases has been remarkably constant across studies, representing approximately two-thirds of patients in several large populations (Alstrom 1950; Juul-Jensen 1964; Gudmundsson 1966; Sander *et al.* 1990; Hauser *et al.* 1993; Forsgren *et al.* 1996; Olafsson *et al.* 1996). Aetiological factors identified in three representative studies are shown in Table 6.5. The relative incidence of different causes varies with age. Among children with epilepsy in whom a cause is found, congenital factors account for 60%, while tumours and trauma are the leading causes in young adults. Among older adults the likelihood of identifying a cause for seizures is higher overall, with the proportion of vascular causes rising to over 50%.

Genetic basis of epilepsy

Based on the epidemiological evidence reviewed above it has been estimated that some 30% of epilepsy has a largely genetic basis (designated idiopathic epilepsy in the current classification system) (Berkovic *et al.* 2006). Acquired causes are identified in a further 30%, the so-called symptomatic

Table 6.5 Aetiological factors in three studies of new-onset epilepsy (figures are percentages).

Aetiology	UK (Sander <i>et al.</i> 1990)	USA (Hauser <i>et al.</i> 1993)	France (Jallon <i>et al.</i> 2001)	Range
Vascular	15	11	3	3–15
Trauma	3	6	3	3–6

The UK and USA studies were community (general practice)-based and population-based respectively. The French study recruited subjects through specialists working in hospital and community settings. Many worked in private practice and the authors note that this may have biased their study in favour of younger subjects, a factor that might account for the lower proportion of cases in which aetiology was found. The study is included here as it is the only one to have estimated the proportion of cryptogenic and idiopathic aetiological categories.

epilepsies. The remaining cases are those in which a cause is suspected but cannot be identified, the cryptogenic epilepsies. Twin studies have demonstrated that a genetic contribution is strongest in the generalised epilepsies but is also significant for localisation-related epilepsies (Berkovic *et al.* 1998; Vadlamudi *et al.* 2004). Likewise, family studies have shown that the risk of epilepsy in first-degree relatives of patients with idiopathic epilepsy is higher than that in those with symptomatic epilepsy, which is still greater than in relatives of controls (Ottman *et al.* 1996). Thus, there is clear evidence that genetic factors play a role even in symptomatic epilepsy. These findings have led to the view that the relationship between genetic and acquired ('environmental' in genetic parlance) factors in the aetiology of epilepsy is best conceived of as a continuum (Sander *et al.* 1990; Berkovic *et al.* 2006). At one end of the spectrum are the relatively rare epilepsy syndromes for which single gene defects have been found. At the other are cases in which acquired lesions are the overriding factor and genetic predisposition may have little influence. In the middle lie the vast majority of patients for whom some interaction between genetic and environmental factors is operative.

Like any other common medical disorder the most important genetic factors in epilepsy are likely to be polygenic, with multiple susceptibility genes contributing to overall risk. Individual susceptibility genes may confer risk for epilepsy in general and/or for certain epilepsy syndromes specifically, with the final phenotype being the result of a complex interaction between genes and environment (Johnson & Sander 2001). As yet, no susceptibility genes have been clearly identified. However, promising avenues for

identifying such genes stem from studies of rare families with inherited epilepsy syndromes in which specific mutations have been discovered. Almost all the genes identified so far have been related to ion channel function and it seems likely that susceptibility genes will act, either directly or as modifiers, through similar mechanisms.

Identified genes

Epilepsy syndromes for which mutations have been identified are shown in Table 6.6. Comprehensive reviews have been provided by Steinlein (2004) and Berkovic *et al.* (2006). Only a brief description of the more common syndromes affecting adults is given here. *Generalised epilepsy with febrile seizures plus*, now widely referred to as GEFS+, includes a spectrum of clinical phenotypes. The core features are febrile seizures and febrile seizures that persist into later childhood (FS+). Otherwise the prominent seizure type is usually generalised, although partial seizures may also be seen and a clinical picture consisting of TLE alone in some family members has been reported recently (Scheffer *et al.* 2007). *Familial autosomal dominant lateral temporal lobe epilepsy with auditory features* is characterised by neocortical temporal lobe seizures that are usually simple partial and feature auditory, sometimes visual, aura. The clinical characteristics of *autosomal dominant nocturnal frontal lobe epilepsy* are as implied by its name. Specific mutations in this disorder have been differentially associated with response to carbamazepine treatment, raising the prospect that increased understanding of the genetic basis for these syndromes may shed light on the mechanisms underlying response and resistance to antiepileptic drug treatment (Sisodiya 2005).

Table 6.6 Epilepsy syndromes for which genetic mutations have been identified. (Adapted from Berkovic *et al.* 2006 with permission.)

Monogenic idiopathic epilepsy	Associated genes
<i>Voltage-gated channelopathies</i>	
Benign familial neonatal seizures	K ⁺ channel genes: <i>KCNQ2</i> , <i>KCNQ3</i>
Benign familial neonatal–infantile seizures	Na ⁺ channel genes: <i>SCN2A</i>
Generalised epilepsy with febrile seizures plus (GEFS+)	Na ⁺ channel genes: <i>SCN1B</i> , <i>SCN1A</i>
Severe myoclonic epilepsy of infancy	Na ⁺ channel genes: <i>SCN1A</i>
Autosomal dominant lateral temporal lobe epilepsy with auditory features	K ⁺ channel subunit: <i>LG/1</i>
<i>Ligand-gated channelopathies</i>	
Autosomal dominant nocturnal frontal lobe epilepsy	Nicotinic acetylcholine receptor subunit genes: <i>CHRNA4</i> , <i>CHRNA2</i>
Idiopathic generalised epilepsy with GEFS+	GABA receptor subunit gene: <i>GABRG2</i>
Familial juvenile myoclonic epilepsy	GABA receptor subunit gene: <i>GABRG1</i>

Table 6.7 Principal causes of progressive myoclonic epilepsy. (Adapted from Shahwan *et al.* 2005 with permission.)

	Age onset	Seizure type	Ataxia	Dementia	Genetic basis	Diagnostic test
Unverricht–Lundborg disease	6–15	Myoclonus +++ Other generalised seizures	Mild and late	Mild and late	Autosomal recessive	Genetic testing
Lafora body disease	12–17	Myoclonus, generalised seizures and occipital seizures	Early	Rapidly progressive	Autosomal recessive	Skin biopsy
MERFF	Adolescence to early adulthood	Myoclonus	Variable	Variable	Mitochondrial	Muscle biopsy
NCL	Infant to adult	Variable	Variable	Rapidly progressive	Autosomal recessive, except adult form (Kufs) which is autosomal dominant	Electron microscopy for intracellular inclusions in eccrine secretory cells, muscle and rectal biopsy
Sialidoses	Juvenile to adult	Myoclonus	Gradual	Variable	Autosomal recessive	Fundoscopy/urinary and white cell enzyme assays
DRPLA	Variable	Myoclonus and other generalised seizures	Progressive	Progressive	Autosomal dominant	Genetic testing

DRPLA, dentatorubral-pallidoluysian atrophy; MERFF, myoclonic epilepsy with ragged red fibres; NCL, neuronal ceroid lipofuscinosis.

Epilepsy occurring in hereditary disorders

A great number of inherited disorders are associated with seizures (Beghi 2004). These include chromosomal abnormalities (e.g. Down's syndrome and fragile X), genetic syndromes with multiorgan effects (e.g. neurofibromatosis and tuberous sclerosis), neurodevelopmental disorders, and certain neurodegenerative disorders. In most cases, seizures probably arise through structural cerebral abnormalities or systemic metabolic effects, rather than through direct genetic epileptogenic mechanisms. Abnormalities of cortical devel-

opment are described in the subsequent section. Seizures are a cardinal feature of a number of rare inherited metabolic disorders known collectively as the progressive myoclonic encephalopathies (PMEs), described briefly below.

The PMEs are a group of rare disorders characterised by myoclonic seizures, tonic-clonic seizures and progressive neurological deterioration, typically with ataxia and dementia (Table 6.7). Most of the underlying disorders have a genetic component. Well-characterised causes include Unverricht–Lundborg disease, Lafora body

disease, myoclonic epilepsy with ragged red fibres, neuronal ceroid lipofuscinosis, sialidoses, and dentatorubral-pallidoluysian atrophy (Shahwan *et al.* 2005). Myoclonus in PME is often multifocal and stimulus-sensitive, being precipitated by posture, action or specific external stimuli such as light, sound and touch. The face and extremities are typically affected and massive bilateral myoclonus affecting the limbs may cause falls and injury.

Unverricht-Lundborg disease is the most common cause of PME. It presents between 6 and 15 years of age with stimulus-sensitive myoclonus and other generalised seizures. Ataxia and mild dementia may develop later.

Lafora body disease presents between 12 and 17 years of age and may initially be indistinguishable from idiopathic generalised epilepsy. In addition to myoclonus and generalised seizures, occipital seizures with transient blindness and visual hallucinations are seen and provide a clue to the correct diagnosis. Cognitive decline, often with prominent emotional disturbance, and ataxia are seen early in the course of the disorder. Most patients die within 10 years of onset.

Myoclonic epilepsy with ragged red fibres is a mitochondrial disorder that presents in adolescence or early adulthood with proximal muscle weakness, neuropathy, ataxia, deafness, seizures and intellectual decline. Other clinical features may include short stature, cardiomyopathy, lipomas and diabetes. There is some overlap with a related disorder, mitochondrial encephalopathy with lactic acidosis and stroke-like episodes (MELAS). MELAS presents in early childhood with shortness of stature and any one of the core features within the acronym. Lactic acidosis may be provoked by exercise or intercurrent illness and is associated with nausea, vomiting and coma leading to an episodic presentation of symptoms.

Neuronal ceroid lipofuscinoses are characterised by accumulation of abnormal lipopigments in lysosomes. Infantile, juvenile and adult-onset (Kufs disease) forms are seen, each with distinct genetic causes. Most are autosomal recessive, although Kufs disease may be autosomal dominant. Two forms of sialidosis are rare causes of PME. They are associated with a variety of autosomal recessive mutations affecting the lysosomal sialidase enzyme and have a variable onset from neonatal to early adult. The cherry-red spot myoclonus syndrome (sialidosis type I) is associated with characteristic appearances on fundoscopy.

Dentatorubral-pallidoluysian atrophy is an autosomal dominant disorder that may present with ataxia, choreoathetosis, myoclonus, epilepsy, dementia and psychiatric disorder. It may closely resemble Huntington's chorea. It is caused by an unstable CAG expansion on chromosome 12p13.31.

Other very rare causes of PME. These include the juvenile form of Huntington's disease, early-onset Alzheimer's disease, Hallervorden-Spatz disease and coeliac disease.

Epilepsy due to birth injury or congenital malformations

Complications of pregnancy and delivery may damage the brain and lead to epilepsy. Most often the seizures will be declared in infancy or date from very early in childhood. Anoxia is an important cause of damage, likewise direct trauma leading to cerebral haemorrhage. However, the risk of epilepsy associated with complications of pregnancy and birth have probably been overstated in the past. The National Collaborative Perinatal Project (Nelson & Ellenberg 1986) examined hundreds of perinatal factors in 2000 children, around 1% of whom had developed epilepsy by 7 years of age. The only significant factors concerning perinatal history were neonatal seizures and being small for gestational age. Congenital malformations (cerebral and non-cerebral) and a family history of certain neurological disorders were the major predictors of epilepsy. A large proportion of children with spasticity, infantile hemiplegia or severe mental defect will suffer from seizures. Covert brain injury without such gross defects is likely to account for seizures in many more. Overall, epilepsy occurs in some 50% of patients with cerebral palsy and the risk rises to over 70% if there is coexistent learning difficulty (Wallace 2001). Both partial and generalised seizures are seen.

Congenital disorders and developmental defects may likewise be found in epilepsies of early onset, and are increasingly demonstrated in cases of adult onset as well. The types of pathology responsible are legion, including porencephaly, tuberous sclerosis and arteriovenous malformations (Sturge-Weber and von Hippel-Lindau syndromes). Particular attention has recently been focused on malformations due to abnormal cortical development, formerly known as cortical dysgenesis. A system of classifying these cerebral malformations has been proposed that divides the disorders into three main categories depending on which aspect of neurodevelopment is primarily affected: cell proliferation, neuronal migration or cortical organisation (Barkovich *et al.* 2001). In many cases a genetic basis for these disorders is either suspected or has been established and sporadic genetic abnormalities (mutations) have also been identified. Other cases may derive from environmental insults to the brain.

The advent of high-resolution MRI has enabled some forms of cortical developmental abnormality to be detected by neuroimaging. It is now clear that these disorders are an important cause of intractable localisation-related epilepsy and are likely to account for many cases that might previously have been regarded as cryptogenic. In a survey of 341 adults with chronic partial epilepsy from the National Hospital, Queens Square, London, cortical dysgenesis emerged as the second most common cause of epilepsy after hippocampal sclerosis, account-

ing for 12% of cases (Li *et al.* 1995). In a study of 100 adults with refractory epilepsy associated with cortical maldevelopment, the median age at onset was 10 years but in 30 patients the onset was in adulthood (Raymond *et al.* 1995). The great majority of these patients had previously been labelled as suffering from 'cryptogenic' epilepsy. In three-quarters the dysgenesis was established by MRI, and in the remainder by histological examination of surgical or post-mortem material.

Sisodiya (2004) discusses the malformations of cortical development most commonly identified in patients with epilepsy.

Focal cortical dysplasia is probably the most common malformation reported in MRI series and is an important cause of non-familial partial epilepsy arising in the first decade. Seizures are usually unresponsive to drug treatment, and surgery after appropriate investigation may result in freedom from seizures in up to 50% of carefully selected patients.

Periventricular heterotopia. In this malformation, nodules of grey matter representing groups of neurones that have failed to migrate are seen. Most cases are attributable to an X-linked disorder but sporadic cases and non-sex-linked forms have also been described. The typical patient is female and of normal intellect with seizures beginning in the second decade. Surgical treatment is usually not possible and specialist genetic counselling may be appropriate.

Polymicrogyria. This denotes the presence of an area of multiple abnormally small gyri. The abnormality may be unilateral or bilateral and may occur on its own or as part of a syndrome with multiple congenital abnormalities. Polymicrogyria may occur in association with schizencephaly, an abnormality characterised by the presence of a transcortical cleft. Surgical resection of polymicrogyral abnormalities is rarely successful in controlling epilepsy, probably because neighbouring areas of cortex are also abnormal and implicated in epileptogenesis.

Subcortical band heterotopia. A layer of neurones that failed to migrate fully to the cortex is found in the white matter just under the cortical mantle. More severe disruption of neuronal migration may result in the complete failure of neurones to reach the cortex, giving the cortex an abnormally smooth appearance (lissencephaly) with gyri being either flat and few (pachygyria) or absent (agyria). X-linked and autosomal genetic causes have been identified. Female carriers of the X-linked disorder may have learning difficulties and epilepsy but lack subcortical band heterotopias. Surgery is usually unhelpful and genetic counselling is an important aspect of management.

Dysembryoplastic neuroepithelial tumours (DNETs). These are some of the commonest types of tumour in epilepsy (Daumas-Duport *et al.* 1988; Raymond *et al.* 1994). They are

classified as malformations arising from abnormal cell proliferation. DNETs are associated with partial seizures with onset before age 20, usually much younger. The lesions are predominantly intracortical, usually involving the frontal or temporal lobes, and the MRI picture of a cystic well-circumscribed lesion of mixed signal characteristics is sometimes sufficiently distinctive to be diagnostic. Characteristics of the tumour include a multinodular architecture, calcification, and cellular polymorphism with an admixture of glial cells, neuronal cells and sometimes germinal matrix components. DNETs may sometimes be difficult to distinguish from low-grade gliomas, even with histology, and long-term monitoring with MRI may be indicated. Malignant transformation of DNETs is currently thought to be very rare. DNETs may be associated with other epileptogenic lesions, including other malformations of cortical development and mesial temporal sclerosis. Seizures are often refractory to medical treatment but surgery, after appropriate detailed presurgical assessment, offers an excellent chance of seizure freedom.

Post-traumatic epilepsy

Head injury is a common cause of epilepsy in young adults. The underlying pathology may be a small cicatrix due to organisation of a circumscribed and superficial haemorrhage, or a more extensive glial reaction with focal atrophy and distortion of brain tissue demonstrable on neuroimaging (see Chapter 4).

The development of post-traumatic epilepsy can be profoundly disabling and has important medicolegal implications. Guidance towards the likelihood of its appearance in an individual case is therefore important. Because seizures arising at different times after head injury have different implications for prognosis, in particular for the likelihood of developing epilepsy, it is useful to distinguish between immediate seizures (occurring within seconds or minutes of the injury), early seizures arising during the period when the patient is recovering from the acute injury (by convention usually regarded as the first week), and late seizures (Frey 2003). Immediate seizures may go unobserved and the underlying mechanisms and implications remain uncertain. They are widely regarded as benign. Approximately 90% of seizures arising in the first 4 weeks after head injury do so in the first week (Annegers *et al.* 1998). These early seizures have a better prognosis with a lessened tendency to persist than late seizures (Jennett, W.B. 1969; Jennett, B. 1975; Annegers *et al.* 1998). Early seizures are commonly focal motor attacks and, in contrast to seizures which develop later, temporal lobe seizures are rare.

In an important population-based study, Annegers *et al.* (1998) report the incidence of unprovoked seizures in 4541 adults and children with traumatic brain injury, characterised by loss of consciousness, post-traumatic amnesia (PTA) or skull fracture, followed for over 10 years. Unprovoked seizures were defined as those occurring after recovery from

Table 6.8 Standardised incidence ratios of unprovoked seizures following brain injury. (From Annegers *et al.* 1998.)

Number of years after brain injury	Standardised incidence ratio for unprovoked seizures (95% CI)
<i>Mild injury (LoC or PTA <30 min)</i>	
<1	3.1 (1.0–7.2)
1–4	2.1 (1.1–3.8)
5–9	0.9 (0.3–2.6)
≥10	1.1 (0.5–2.1)
<i>Moderate injury (LoC or PTA 30 min to 24 hours and/or skull fracture)</i>	
<1	6.7 (2.4–14.1)
1–4	3.1 (1.4–6.0)
5–9	3.0 (1.2–6.2)
≥10	1.8 (0.8–3.6)
<i>Severe injury (LoC or PTA >24 hours, intracranial haematoma or brain contusion)</i>	
<1	95.0 (58.4–151.2)
1–4	16.7 (8.4–32.0)
5–9	12.0 (4.5–26.6)
≥10	4.0 (1.1–10.2)

LoC, loss of consciousness; PTA, post-traumatic amnesia.

the acute effects of injury (over 1 week from injury) in the absence of an acute CNS insult. Head injuries were classified by severity into three groups. Mild injuries were those in which the duration of loss of consciousness or PTA was less than 30 minutes. Moderate injuries were those accompanied by loss of consciousness or PTA of between 30 minutes and 24 hours or associated with skull fracture. Severe injuries were characterised by loss of consciousness or PTA of more than 24 hours, intracranial haematoma or brain contusion (based on the presence of focal neurological signs or observation during surgery). Incidence rates for unprovoked seizures were compared with rates for the general population. In line with previous reports (Jennett 1975), the main finding was that severity of injury was strongly correlated with the risk of subsequent epilepsy and also with the length of time following injury for which the patient remained at elevated risk of seizures (Table 6.8). Over the follow-up period the incidence of unprovoked seizures was 1% following mild injury, 2% following moderate injury and 12% in the severe injury group. Patients with mild injury had a marginal 1.5-fold increased risk of seizures compared with the general population and were not at any appreciably greater risk of epilepsy 5 years after injury if seizures had not developed by that time. In contrast, patients with severe brain injury had a 17-fold increased risk of seizures and remained at increased risk of new-onset seizures beyond 10 years after the injury. The strongest predictors of seizures were, in descending order, brain contusion, subdural haematoma, skull fracture, loss

of consciousness or PTA of more than 24 hours, and age over 65. Early seizures (in the first week after injury), often regarded as predictive of subsequent epilepsy, were associated with subsequent unprovoked seizures but when other risk factors were taken into account the presence of early seizures was no longer a significant prognostic indicator. This latter point was underlined by the observation that of 36 patients with mild head injury who had an early seizure, none subsequently developed epilepsy.

These findings are broadly consistent with the earlier study by Jennett (1975), although he did find that seizures in the first week were significant predictors of subsequent epilepsy. In his detailed examination of risk factors, Jennett found the incidence of epilepsy after head injury to be 1%. He found that a seizure occurring within the first week raised the incidence of subsequent epilepsy to 25%. The occurrence of a depressed skull fracture raised the incidence to 15%, and an intracranial haematoma to 31%. A depressed fracture associated with a PTA in excess of 24 hours led to an incidence of 32%. If in addition these features were associated with a seizure within the first week, the incidence was 57%.

Penetrating injuries carry a much higher incidence of post-traumatic epilepsy, reported as being 30–50% (Russell & Whitty 1952; Walker & Jablon 1961; Salazar *et al.* 1985). The risk of seizures after penetrating injury, as with closed head injury, is highest in the first year but remains elevated for 10 years or more. In Russell and Whitty's series, the highest incidence was from wounds in the central regions of the brain (parietal 65%, motor and premotor cortex 55%), with a diminished incidence towards the poles (prefrontal 39%, temporal 38%, occipital 38%). Multilobar injuries are associated with the highest incidence of epilepsy (Caveness *et al.* 1979).

Caveness *et al.* (1979), reviewing studies from the First and Second World Wars and the Korean and Vietnam wars, showed that the incidence of post-traumatic epilepsy had remained substantially the same despite marked improvements in the management of acute head injuries. With regard to prognosis, experience from the Korean campaigns shows that approximately half of the patients with seizures had ceased to have them within 5–10 years, and that in half of the remainder the fits proved to be intractable. Prophylactic treatment with antiepileptic drugs may reduce the incidence of early seizures after closed or penetrating head injury but is not effective in preventing late seizures and is likely to exacerbate cognitive deficits and impede rehabilitation (Beghi 2003).

Postinfective epilepsy

Infections of the brain and its meningeal coverings may lead to seizures in the acute stage, or produce scarring that becomes the source of seizures some considerable time later. Encephalitis is more likely to be followed by epilepsy than meningitis. In a population-based follow-up study,

Annegers *et al.* (1988) found that the risk of epilepsy was dependent on the type of infection and the presence of seizures during the acute illness. Thus, the 20-year risk of seizures following encephalitis with early seizures was 22% (10% if there were no early seizures). The corresponding figures for bacterial meningitis were 13% with early seizures and 2.4% without them. Seizures most frequently occurred in the first 5 years after the initial illness but the risk remained elevated for at least 15 years. The risk of epilepsy following aseptic meningitis was not increased compared with the general population. Over one-third of patients will develop epilepsy after a cerebral abscess (Koszewski 1991). The incidence of epilepsy due to covert brain involvement during the course of mumps, whooping cough and other infectious diseases of childhood is impossible to determine. Epidemiological studies have failed to demonstrate any association between vaccination and epilepsy (Gale *et al.* 1994). Neurosyphilis must not be overlooked as a cause of late-onset epilepsy. Parasitic cysts within the brain are an important cause of seizures in certain parts of the world (see Chapter 7).

Epilepsy due to cerebrovascular disease

Stroke is an important cause of epilepsy beginning in later adult life, and asymptomatic cerebral infarction is likely to account for many cases of cryptogenic epilepsy in the elderly. Between 2% and 4% of patients will experience a seizure within 24 hours of a stroke (So *et al.* 1996; Burn *et al.* 1997). The risk of later seizures is highest in the first year after stroke, but remains elevated compared with the general population for over 5 years, at which time 7–11% will have experienced a seizure. Approximately half of these seizures are isolated events. When seizures recur they are usually infrequent and rarely pose a major problem. The risk of seizures is greater following intracerebral or subarachnoid haemorrhage than following cerebral infarction, with the exception of total anterior circulation infarction following which up to one-third of patients will suffer a seizure (Burn *et al.* 1997). The likelihood of recurrent seizures (epilepsy) is increased in those with seizures occurring in the first 24 hours and if there is a further stroke (So *et al.* 1996).

Other vascular abnormalities

Approximately 20% of patients with arteriovenous malformations will develop seizures (Crawford *et al.* 1986a). The risk of seizures is higher in younger patients and following haemorrhage. In Crawford's series, the risk of seizures was doubled in those who had been treated neurosurgically (Crawford *et al.* 1986b). Cavernous haemangiomas have been associated with a similar risk of seizures (Kondziolka *et al.* 1995). These hamartomatous vascular lesions are relatively well circumscribed and the outcome after surgical resection may be better than for arteriovenous malformations (Kitchen *et al.* 2004).

Epilepsy due to cerebral tumour

A space-occupying lesion may first declare itself with seizures and must be suspected in late-onset epilepsy. Tumours in the so-called silent regions of the brain naturally present a special hazard in this regard. Approximately 40% of patients with fits due to tumour will have seizures as the first symptom (Chadwick 1993). Low-grade tumours are more likely to present with seizures than rapidly invasive tumours (Cascino 1990). Both primary and secondary tumours can be responsible.

Epilepsy due to degenerative disorders

In a population-based study from the Rochester Epidemiology Group, Alzheimer's disease was associated with a sixfold increased risk of unprovoked seizures (Hesdorffer *et al.* 1996). Generalised seizures predominate, although there is also an increased risk of partial seizures. Myoclonus is a late manifestation in up to 10% of patients with Alzheimer's disease confirmed at post-mortem (Hauser *et al.* 1986). Seizures may occur as early as 3 months after Alzheimer's disease is diagnosed, but the incidence rises as the disease progresses. In a prospective study of 44 patients with mild probable Alzheimer's disease, Romanelli *et al.* (1990) reported a cumulative incidence of 16% over 7.5 years. Seizures tend to be infrequent (average of about two annually), and are rarely associated with significant problems (McAraevey *et al.* 1992). The Rochester study quoted above found that patients with dementia other than Alzheimer's disease had an eightfold increased risk of seizures, although associations with specific diagnoses in this group were not specified. Patients with multi-infarct dementia were under-represented in this study as subjects with a history of stroke were excluded, but it seems likely that this condition is associated with a relatively high risk of seizures.

Epilepsy due to drugs and toxins

Chronic alcohol use is a well-established risk factor for epileptic seizures. In the UK general practitioner-based epidemiological study of epilepsy, alcohol was judged to be a significant factor in 6% of cases (Sander *et al.* 1990). There is a dose-dependent relationship between daily intake of alcohol and the relative risk of seizures. The increased risk (in men) begins with a daily consumption of about 50 g of alcohol (about 4 units), rising to a 16-fold increased risk with an intake of greater than 200 g/day (Ng *et al.* 1988; Leone *et al.* 1997). Victor and Brausch (1967) reported that 88% of seizures in chronic alcohol abusers occurred within 48 hours of stopping drinking and were therefore related to alcohol withdrawal. Others have been unable to replicate this finding (Ng *et al.* 1988), with 50% of seizures in some series seemingly unrelated to withdrawal (Bartolomei *et al.* 1997). Bartolomei *et al.* (1997) found that such seizures were associated with the presence of other alcohol-related neurological sequelae, and suggested that the seizures may themselves be secondary to

a cumulative neurotoxic effect of chronic alcohol misuse. Heroin use has been associated with a small increased risk of unprovoked seizures in one study (Ng *et al.* 1990). However, most drugs and toxins are associated with acute seizures rather than epilepsy and are therefore considered in the section below describing provoked seizures.

Other causes

Seizures may occur in connective tissue disorders and vasculitides involving the brain. Multiple sclerosis is associated with a threefold increased risk of seizures: Olafsson *et al.* (1999) found that the cumulative incidence of seizures 10 years after diagnosis was 1.9%.

Aetiology of temporal lobe epilepsy

A good deal of interest has centred on the pathological substrate of TLE, since this may be examined in resected brain tissue obtained at temporal lobectomy. A variety of lesions are found: scars, infarcts, small benign tumours of developmental origin (hamartomas) or *mesial temporal lobe sclerosis*. The latter is by far the commonest lesion found at operation, occurring in some 50% of cases, and appears to be the commonest single finding in any epileptic patient who dies a natural death (Falconer & Taylor 1968). The pathogenesis of mesial temporal lobe sclerosis is thus a subject of considerable importance.

The sclerosis consists of dense glial infiltration of Ammon's horn and adjacent structures such as the amygdala and uncus in the medial part of the temporal lobe. It is usually unilateral. The associated epilepsy commonly sets in during the first decade of life, is frequently severe and responds particularly well to surgical resection of the lesion. Initially it was thought to result from birth injury, either through generalised hypoxia or as a result of herniation and compression of the posterior cerebral arteries against the tentorial opening. However, careful studies suggest that this is not so (Ounsted *et al.* 1966; Falconer & Taylor 1968; Falconer 1974). Neither high birth weight nor prematurity predisposes to TLE, and the incidence of birth injury in patients with medial temporal lobe sclerosis has usually been found to be no higher than in other groups with TLE. Nonetheless, Bruton (1988), in an analysis of a large series of resected temporal lobe specimens, found a weakly significant relationship between the presence of the lesion and a history of birth injury, suggesting that the latter may be operative in a small proportion of cases.

A factor that has emerged as especially common is a history of febrile convulsions, often with status epilepticus, occurring in early childhood. This was confirmed in Bruton's study. It was suggested that the anoxia deriving from such episodes, if sufficiently prolonged at this vulnerable period, may cause irreversible damage to the medial temporal lobe structures and result in due course in the sclerotic epileptogenic lesion. A similar lesion can be produced experimentally in adolescent baboons by inducing serial epileptic

attacks or status epilepticus, and as in humans the resulting lesion is usually unilateral (Meldrum *et al.* 1973, 1974).

However, the relationship between febrile convulsions and TLE remains one of the most controversial areas in epilepsy (Waruiru & Appleton 2004). While an association between hippocampal sclerosis and febrile convulsions, particularly prolonged convulsions with focal features, has been a consistent finding (Trinka *et al.* 2002), a causal relationship has not been established. There are three possible explanations for the association: (i) febrile convulsions may cause hippocampal damage in a previously normal individual; (ii) febrile convulsions arising because of some pre-existing genetic or structural predisposition to epilepsy may cause hippocampal sclerosis; or (iii) hippocampal pathology, occurring in isolation or with more widespread cerebral pathology, may precede and predispose to the development of febrile seizures, which are therefore an epiphenomenon of the underlying cause of the epilepsy. Although studies with animal models, mentioned above, support a causal role for febrile convulsions, prospective studies in children have been unable to identify hippocampal sclerosis following prolonged febrile seizures (Scott *et al.* 2003; Tarkka *et al.* 2003). However, larger studies may be required to resolve this issue. In support of the third possibility, recent neuropathological data from 33 children with intractable TLE found cortical dysplasia in three-quarters of those patients with a history of febrile convulsions (Porter *et al.* 2003). Also, in an MRI study of adults with TLE, of those with hippocampal sclerosis, two-thirds had no history of febrile convulsions and 15% had additional evidence of cortical dysgenesis (Kuks *et al.* 1993).

Causes of acute symptomatic seizures

Acute symptomatic, or provoked, seizures have many different causes. Among acute CNS insults, the most frequent causes are head trauma, cerebrovascular disease and infection (Annegers *et al.* 1995). Delanty *et al.* (1998) have reviewed the large number of systemic medical conditions in which seizures may arise. Important causes include renal and hepatic failure, ischaemic hypoxia, endocrine disorder and electrolyte disturbance. Examples of the latter include hyponatraemia and hypernatraemia, hypomagnesaemia and hypocalcaemia, and hypoglycaemia and hyperglycaemia. Seizures may be the presenting feature of hypertensive encephalopathy. This disorder is associated with oedema in the parietal and occipital lobes caused by a failure of autoregulation of the posterior cerebral circulation. A characteristic posterior leucoencephalopathy, which is reversible, is seen on MRI. A great number of drugs may cause seizures (Garcia & Alldredge 1994). Drugs were implicated in 1.7% of all seizure-related patients attending San Francisco General Hospital over a 10-year period (Messing *et al.* 1984). The most frequent culprits were psychotropics (35%), isoniazid (20%), bronchodilators (10%), stimulants (10%) and insulin (10%). Most, if not all, antidepressant and antipsychotic drugs are

associated with a significant risk of seizures following overdose. However, with the exception of clozapine, the risk of seizures at therapeutic doses is low (Alldredge 1999). Clozapine is associated with a 4% risk of seizures at doses of 600–900 mg daily. The hazards of psychotropics in people with epilepsy have probably been exaggerated (see Psychotropic medication in epilepsy, later in chapter). Organic solvents and poisoning with heavy metals such as lead, mercury and tungsten may also cause seizures.

Aggravating and precipitating factors in epilepsy

Whatever the underlying cause of seizures, certain factors may operate to facilitate attacks. Some are largely idiosyncratic to the individual concerned, as seen in extreme degree in reflex epilepsy (see Syndromes characterised by seizures with specific modes of precipitation, earlier in chapter). Others may be of more general relevance. Some two-thirds of patients with epilepsy report seizure precipitants (Spatt *et al.* 1998; Frucht *et al.* 2000). The most commonly reported trigger is stress (in around 30%) followed closely by fatigue and sleep deprivation. Other precipitants emerging from these self-report studies have been fever or intercurrent illness, alcohol, fasting, caffeine and many more. Changes in the weather were identified as the second most important trigger (30%) in an Austrian study (Spatt *et al.* 1998), while less than 10% of patients attending a tertiary referral centre in the USA identified 'heat and humidity' as significant (Frucht *et al.* 2000). These discrepant findings serve to emphasise that an individual's perception of relevant triggers will be strongly coloured by the many factors, personal and cultural, that shape beliefs concerning illness attribution. Exacerbations of seizures related to the menstrual cycle (*catamenial seizures*) have been identified in careful prospective studies in up to one-third of women (Herzog *et al.* 1997).

The relationship between stress and seizures was investigated by Stevens (1959), who found that an emotionally stressful interview could have a markedly adverse effect on the stability of EEG patterns in a large proportion of epileptics, but was without effect in normal controls. More specifically, Barker and Wolf (1947) illustrated the highly individual triggering that could occur in relation to certain conflict situations. They presented a detailed psychological study of a patient whose epileptic attacks appeared to be related to occasions when his anger broke through customary inhibitory restraints. When interviewed under amobarbital (Sodium Amytal), he expressed mounting rage against his mother, culminating in a seizure with coincident epileptic discharges on the EEG.

Psychiatric disability among people with epilepsy

The majority of patients with newly diagnosed epilepsy will have their seizures fully controlled with antiepileptic drug treatment and are probably not at increased risk of psychiatric disorder. For example, Jacoby *et al.* (1996) studied depression in a community sample of people with epilepsy, nearly

half of whom had been free of seizures for over 2 years. In this seizure-free group the prevalence of depression was only 4%, comparable to what might have been expected in the general population. Depression was found in 10% of patients who reported less than one seizure per month and in 21% of those with more frequent seizures. Time and again, studies of the association between epilepsy and various psychiatric disorders have identified some measure of seizure severity as one of the most important risk factors, and psychiatric disorder is undoubtedly over-represented in people with chronic intractable epilepsy. Among patients being evaluated for epilepsy surgery, for example, over one-third will have a current psychiatric diagnosis and a further third will have a significant past psychiatric history (Manchanda *et al.* 1996). In light of these findings, it is not surprising that studies of the prevalence of psychiatric morbidity in epilepsy have produced widely varying estimates depending on the population studied, as well as the measures and definitions used. Clearly, patients presenting to a psychiatrist, or requiring institutional care, will have a higher frequency of psychiatric and social problems than people with epilepsy attending only their general practitioner (Edeh *et al.* 1990). Equally, patients under supervision in tertiary referral services will be unrepresentative of the wider population.

Some representative data comes from surveys conducted in general practice. Pond and Bidwell (1960) collected information on 245 patients from 14 practices in south-east England. They found that 29% showed conspicuous mental problems and 7% of the total had already had psychiatric inpatient care, which was twice the rate expected in the general population. Edeh and Toone (1987) conducted the Clinical Interview Schedule in 88 patients in general practices in south London; 31% had a history of psychiatric referral and 48% were identified as having significant psychiatric morbidity. The great majority of psychiatric problems were minor affective disorders.

Graham and Rutter's (1968) survey dealt with schoolchildren between the ages of 5 and 14 on the Isle of Wight, and showed a high prevalence of psychiatric disturbance. The entire population of children on the island was screened and 85 cases of epilepsy were discovered (7.2 per 1000); 29% of those with epilepsy, but with no other evidence of a brain lesion ('uncomplicated epilepsy'), showed some psychiatric disorder. When in addition to epilepsy there was other independent evidence of brain damage, the figure rose to 58%. Children with TLE showed significantly more disturbance than children with other epileptic syndromes. These figures could be compared with the prevalence of psychiatric disorder among the rest of the schoolchildren of the island, which emerged at 6.8%. The type of psychiatric disorder shown by the children with 'uncomplicated epilepsy' was closely similar to that seen in other children with psychiatric problems, mainly neurotic disorders or antisocial conduct. Teachers' ratings showed that they were more restless and fidgety and more inclined to aggression than the generality

of schoolchildren, but again these characteristics applied to children with psychiatric disorder even in the absence of epilepsy.

In a careful analysis of causes it was shown that lowered intelligence was unlikely to be a factor. The uncomplicated epileptic group showed a normal distribution of intelligence, likewise the subgroup with TLE. The ongoing handicap of epilepsy alone was unlikely to be responsible, since less than 12% of children with other chronic handicaps (asthma, heart disease, diabetes) showed psychiatric disorder, and in any case many of the children with epilepsy were little incapacitated by it. Widespread community prejudice against epilepsy was thought to be an adverse factor in the epileptic child's development, though many of the sample had nocturnal seizures only and psychiatric disability was not especially frequent in children whose teachers knew of their condition. Thus by exclusion it seemed that an important factor was probably the dysfunction occurring specifically within the brain. In addition the influence of parental handling appeared to be important; an adverse family background, measured in terms of the mother's emotional stability, was significantly more common among the epileptic children with psychiatric disability than in those without.

A number of case-control studies have compared the prevalence of psychiatric disorder in epilepsy and other patient groups. Overall, epilepsy has been associated with higher rates of psychiatric morbidity. However, the differences have not been striking and it seems likely that the chronic disability associated with intractable epilepsy is an important determinant of psychiatric sequelae. Mendez *et al.* (1986) surveyed 503 individuals with epilepsy and 186 with other disabilities attending vocational services for the disabled. Depressive symptoms were more common in the epileptic group, who were also more likely to have received psychiatric treatment. An additional finding was that a history of attempted suicide was four times more common in those with epilepsy (see Epilepsy and suicide, later in chapter). However, this study had considerable problems with selection bias; only one-third of survey questionnaires were returned. In a hospital-based study, Fiordelli *et al.* (1993) used the same Clinical Interview Schedule as Edeh and Toone (1987) to assess 100 outpatients but found a much lower prevalence of 'caseness' (19%), this differing little from controls attending hospital for minor surgical procedures. Depression and anxiety were the commonest problems. The lower prevalence of psychiatric disturbance compared with Edeh and Toone's survey may have reflected the exclusion of patients with IQs below 80, and the exclusion of those with evidence of brain lesions. To the extent that the latter might explain the difference, it would suggest that some of the psychiatric disability encountered in patients with epilepsy is attributable to brain damage rather than to the epilepsy *per se*. Most patients were on monotherapy, usually with carbamazepine, and it was possible to show that polypharmacy carried increased risk of psychiatric disorder. In a population-based case-control study from Iceland, Stefansson *et al.*

(1998) compared International Classification of Diseases (ICD)-9 psychiatric diagnoses among 241 disability claimants with epilepsy and 482 age- and gender-matched disability claimants with cardiorespiratory disease or arthropathy. Patients with learning disability and autism were excluded from the study. The prevalence of psychiatric disorder in the epilepsy group (35%) was not significantly higher than in the non-epileptic disability claimants (30%), although some specific diagnoses, notably non-affective psychoses, were more prevalent in those with epilepsy. Most recently, Ettinger *et al.* (2004) conducted a large postal survey comparing patients with self-reported diagnoses of epilepsy or asthma with healthy controls. Both patient groups had higher rates of depressive symptoms than controls but differences between the patient groups fell short of statistical significance when demographic variables were controlled for in the analysis. However, those with epilepsy were more likely to be unemployed and to report lower quality of life.

Thus, while in the majority of people epilepsy is compatible with normal mental health, psychiatric disturbance is far from uncommon and appears to outstrip that seen in the general population. It is found from a very early age and is accompanied by a great deal of chronic social disability, underlining the importance with which it must be viewed. The genesis of such disability is clearly a complex matter, partly psychological, partly social and partly pathophysiological in origin. In the sections that follow an attempt is made to explore in further detail the forms which psychiatric disability may take, its aetiology and its association with different varieties of epilepsy.

Classification of psychiatric symptoms and syndromes in epilepsy

Fenton (1981) proposed a system for classifying psychiatric disorder in epilepsy that has found widespread use (Table 6.9). Psychiatric presentations in epilepsy may be clearly attributable to the underlying cause of seizures. If this is not the case, there is often an obvious temporal relationship between episodic psychiatric symptoms and seizures. Thus, certain psychiatric presentations may precede seizures, arise as a direct manifestation of an epileptic discharge, or follow seizures. Finally, some patients with epilepsy develop persistent or recurrent psychiatric disorders that appear to be independent of seizure activity, or to at least show a variable relationship to the occurrence of seizures. Most of the presentations in the peri-ictal category are more or less unique to epilepsy (e.g. prodromal symptoms, epileptic aura and postictal psychosis). In contrast, the interictal category includes disorders that would meet standard diagnostic criteria for psychiatric conditions such as depression or schizophrenia, although the prefix 'organic' might be used in recognition of a presumed causal association with epilepsy, e.g. organic depressive disorder, organic psychosis.

Table 6.9 Classification of psychiatric presentations and disorders in epilepsy.

<i>Disorders clearly attributable to the brain disorder causing epilepsy</i>
Learning disability
Specific epileptic syndromes
West syndrome
Lennox–Gastaut syndrome
Epilepsy with continuous spike-and-wave during slow-wave sleep
Progressive myoclonic epilepsies
Cognitive and behavioural manifestations of other acquired causes of epilepsy
<i>Disorders strictly related in time to seizure occurrence</i>
Pre-ictal
Ictal: psychiatric manifestations of seizure activity
Aura
Automatisms
Non-convulsive status epilepticus
Postictal
Delirium
Psychosis
<i>Interictal psychiatric disorders</i>
Affective disorder
Schizophrenia-like psychosis
Personality disorder/behaviour disorder
Dementia
Dissociative seizures

Disorders clearly attributable to the underlying brain disorder causing epilepsy

This category includes patients who have epilepsy of known aetiology in whom the underlying brain pathology is itself associated with psychiatric, cognitive or behavioural manifestations. The neurobehavioural manifestations are judged to be a consequence primarily of the underlying brain disorder rather than of epilepsy. Examples include a number of syndromes affecting children presenting with epilepsy associated with cognitive and behavioural problems. These include West and Lennox–Gastaut syndromes (see Cryptogenic or symptomatic generalised epilepsy syndromes, earlier in chapter) and the PME (see Epilepsy occurring in inherited disorders). The psychiatric disorders seen in children with learning difficulties and epilepsy also fall into this category, as do the cognitive and behavioural sequelae of dementias, focal brain pathologies and other causes of epilepsy in adults not considered further in this chapter.

Disorders temporally related to the occurrence of seizures

Pre-ictal disorders

The term ‘prodrome’ refers to a variety of subjective symptoms occurring in the hours or even days leading up to a seizure. They herald seizure onset but do not form part of it (Blume *et al.* 2001). Prodromal symptoms are distinguished

from the aura of partial seizures by their gradual onset and prolonged duration. Non-specific, ill-defined feelings of malaise with headache, tiredness, irritability and dysphoria are typical but there may be more pronounced affective symptoms, in particular depression. Prodromal symptoms are reported by 7–20% of patients and are more common among patients with localisation-related epilepsy (Hughes *et al.* 1993; Schulze-Bonhage *et al.* 2006). It is important to note, however, that prodromes are also described by patients with generalised epilepsy syndromes and they should not be interpreted as evidence of focal brain disorder. The prodrome phenomenon has been little studied and the pathophysiological basis for these symptoms is not understood.

Ictal disorders

Epileptic aura

The many varieties of epileptic aura and their regional affiliations have been described in the section on the anatomically defined localisation-related epilepsy syndromes. Just as an epileptogenic lesion in the primary motor cortex may give rise to focal clonic muscle jerking, so other discharges, especially those arising in the temporal lobes, may result in purely mental phenomena. In a simple partial seizure such ictal psychiatric phenomena may be the only manifestation of the seizure, while in complex partial seizures they constitute the aura that precedes clouding of consciousness and loss of awareness. They are not, of course, psychiatric disorders at all. Their importance lies in the fact that they may occasionally be mistaken for the paroxysmal symptoms of functional psychiatric illness. Hallucinations and odd aberrations of thought, such as forced thinking or crowding of thoughts, may raise the possibility of psychosis. A diagnosis of primary depersonalisation disorder might be entertained if this is the principal symptom. Most commonly of all, ictal anxiety may be mistaken for panic disorder.

In most cases the distinction between epileptic aura and psychiatric symptoms is straightforward if the cardinal features of epileptic phenomena are borne in mind: they are brief, paroxysmal and highly stereotyped. In taking a history, the presence of other more obviously epileptic phenomena should be sought. The patient should be questioned carefully about the precise sequence of events during the attacks and asked specifically about other subjective experiences. Two or more aura symptoms often occur together, for example anxiety and an epigastric aura, in which case it is the stereotyped combination and sequence of events that gives the diagnosis. An informant history is essential and often provides crucial evidence. It is important to ask specifically about motor features such as subtle dystonic posturing and automatisms. These may go entirely unnoticed by the patient even if remaining fully alert throughout the seizure (Biraben *et al.* 2001). There may also be brief periods of clouding of consciousness for which the patient has no memory but

which are quite obvious to an observer. Additional features helpful in distinguishing ictal anxiety from panic disorder are (i) the autochthonous nature of ictal fear which arises 'of itself', independent of situational triggers; (ii) the intense and unique quality of the emotion, which is typically quite distinct from the patient's experience of 'normal' anxiety; and (iii) the cognitive symptoms of panic, such as a fear of dying or of suffocation, are usually absent in ictal fear.

Epileptic automatisms

Automatisms have conventionally been regarded as the behavioural concomitants of ictal or postictal delirium and indeed in most cases this is exactly what they appear to be. However, clear-cut examples of oro-alimentary automatisms (lip-smacking, swallowing movements) have now been documented during simple partial seizures in patients who show no evidence of clouding of consciousness (Alarcon *et al.* 1998; Biraben *et al.* 2001). These observations suggest a more sophisticated model of automatisms is required. They also explain the rather qualified tone of the definition recently put forward by the ILAE (Blume *et al.* 2001), which states that an automatism is 'a more or less coordinated, repetitive motor activity usually occurring when cognition is impaired and for which the subject is usually amnesic afterwards'. The terms used to describe automatisms are listed in Table 6.10. It is noteworthy that two descriptive terms, hypokinetic and dysphasic, included in the current ILAE glossary represent

something of a departure from the usual meaning of automatism (and indeed the ILAE's own definition) in that they describe neurological deficits rather than positive motor activity.

The great majority of automatisms are brief, lasting from a few seconds to several minutes, although occasional examples have lasted for up to 1 hour. Knox (1968) found that 80% occupied less than 5 minutes, and another 12% less than 15 minutes. Automatisms may range from simple movements, such as the oro-alimentary features mentioned above, to more complex semi-purposeful actions. These may be relatively self-contained and stereotyped, or be influenced by environmental factors and therefore variable from one occasion to the next. The subject may merely continue with what he was doing, a dazed expression and sudden inaccessibility being the only indications of the seizure. Or there may be no more than some regular stereotyped manoeuvre such as pulling at the clothes, passing a hand over the face or fumbling with objects near at hand. Brief automatisms can in fact pass unnoticed by onlookers. In more extended attacks patients perform a whole sequence of related actions: walking about the room, searching in drawers, moving objects or attempting to remove their clothing. The actions tend to be repetitive, fumbling and clumsy, but are sometimes reasonably well coordinated. The apparent purposefulness behind the movements also varies considerably. Intentions are usually poorly conceived and executed, but

Table 6.10 Terms describing automatisms.

Oro-alimentary	Lip-smacking, lip-pursing, chewing, licking, tooth grinding or swallowing
Mimetic	Facial expression suggesting an emotional state, often fear
Manual or pedal	Indicates principally distal components, bilateral or unilateral Fumbling, tapping, manipulating movements
Gestural (often unilateral)	Fumbling or exploratory movements with the hand directed toward self or environment Movements resembling those intended to lend emotional tone to speech
Hyperkinetic	Involves predominantly proximal limb and axial muscles producing irregular sequential ballistic movements such as pedalling, pelvic thrusting, thrashing, rocking movements Increase in rate of ongoing movements or inappropriately rapid performance of a movement
Hypokinetic	Decrease in amplitude and/or rate or arrest of ongoing motor activity
Dysphasic	Impairment of language without dysfunction of relevant primary motor or sensory pathways, manifested as impaired comprehension, anomia, paraphasic errors or a combination of these
Gelastic	Bursts of laughter or giggling, usually without an appropriate affective tone
Dyscrastic	Bursts of crying
Vocal	Single or repetitive utterances consisting of sounds such as grunts or shrieks
Verbal	Single or repetitive utterances consisting of words, phrases or brief sentences
Spontaneous	Stereotyped, involve only self, virtually independent of environmental influences
Interactive	Not stereotyped, involve more than self, environmentally influenced

are sometimes successfully carried through even though inappropriate to the situation. The following examples described by Lennox (1960) are typical.

A woman abruptly ceased her conversation, assumed a strained worried expression and walked away. Led into an adjoining room, she walked quickly from place to place saying 'I must get my coat'. After 5 minutes she consented to sit down and converse, asking what she should do about her affairs, but seemingly not satisfied with the answers because her questions would be repeated again and again. She had no recollection of this seizure or of the postictal conversation nor, in fact, of anything until after she awoke the next day.

While in a physician's office a patient suddenly stopped talking and stared into space. He slumped in his chair for a brief moment, then sat up and began to rub his abdomen with both hands. A flashlight was shone into his eyes and he turned away. He began to rummage about the desk as if looking for something. When questioned as to what he wanted, he said 'I wanna, I wanna'. At this point he took a cigarette from his packet, lit it and started to smoke. He then got up from his chair, walked out of the office and wandered down the hall, opening all the doors and saying 'I want a toilet'. Next, he walked down the hall but could not be distracted by any outside contact. He then lay on the bed and appeared to regain contact gradually.

A policeman directing traffic walked to a waiting car, opened the door, opened and examined the contents of the woman driver's handbag, then returned the bag and went back to his post. The woman reported the occurrence and the policeman denied knowledge of it. Subsequent seizures were predominantly convulsive.

To the onlooker, in the great majority of automatisms, the subjects are clearly out of touch with their surroundings. Typically they look somewhat dazed and vacant, and often anxious and tense. When spoken to there may be no response or they may mumble incoherently or answer quite irrelevantly. Attempts at distraction are likely to be resisted, and interference may meet with opposition amounting on rare occasions to combative behaviour. Only very rarely are patients reported in whom judgement and awareness were seemingly maintained during attacks. Hughlings Jackson (1889) recorded the case of a physician who apparently per-

sisted with reasonably competent behaviour during some of his automatisms: in one he continued to write a prescription though the details of dosage were incorrect, and in another he correctly diagnosed a case of pneumonia during an episode for which he was afterwards completely amnesic. Such examples are exceptional and should perhaps be accepted with reserve. It is now widely agreed that behaviour is unlikely ever to be entirely normal, or conversation rational, while the attack is in progress (Jasper 1964; Fenton 1972). Even when complex coordinated activities are maintained, these are usually inappropriate in some respects to the immediate situation, and judgement will be seen to have been impaired. Subjectively the main feature noted by the patient is amnesia for the period of the automatism, and sometimes for a period after its termination as well. The amnesia is usually total, though a vague and muddled awareness of some parts may occasionally be retained.

Non-convulsive status epilepticus

Non-convulsive status epilepticus is a term used to denote conditions in which prolonged electrographic seizure activity results in non-convulsive seizure symptoms (Shorvon 1994; Walker *et al.* 2005). In epidemiological studies prolonged duration is usually operationally defined as over 30 minutes, although this time limit is arbitrary. Non-convulsive status epilepticus is under-recognised but probably accounts for around 40% of all status epilepticus. In older children and adults the most common forms are complex partial status and absence status. Mental state abnormalities and behavioural disturbance may be the most conspicuous features and these forms of status are not infrequently mistaken for psychiatric disorder.

Partial non-convulsive status epilepticus. Complex partial status is the most common form of non-convulsive status. It usually arises in a patient known to have epilepsy or in the context of an acute cerebral insult (Drislane *et al.* 1999). A recognised pattern in patients with intractable localisation-related epilepsy is for complex partial status to follow on from a secondarily generalised seizure. The classical picture is one of fluctuating delirium with motor automatisms. Patients characteristically cycle between a state of partial responsiveness and one of more severely impaired consciousness, with behavioural arrest and motor features. Sometimes the fluctuating nature of the delirium is obviously attributable to repeated complex partial seizures with incomplete recovery between seizures. In other cases, however, there is a more or less continuous state of impaired consciousness. Motor signs are focal and usually intermittent, with dystonia or myoclonic jerking that may be confined to a hand or foot, or may involve complex posturing and automatisms. Adversion of the head and eyes is common. Spontaneous nystagmus may be a helpful clinical sign. Behavioural changes range from psychomotor retardation

to states of marked agitation and affective disturbance. The usual picture, however, is of a patient who seems relatively composed but withdrawn and inaccessible. Speech and behaviour seem sluggish, restless, repetitive and disorganised. Anxiety is the most common affective change and may be intense, accompanied by severe agitation. There may be psychotic symptoms including visual or auditory hallucinations and paranoid ideation and a clinical picture resembling catatonia has been described (Toone 1981; Lim *et al.* 1986). However, the presence of delirium is usually unmistakable and the distinction between complex partial status and functional psychiatric disorder should rarely be difficult. In this respect, prolonged seizures without impairment of consciousness, as found in simple partial status epilepticus, are potentially more problematic from a diagnostic point of view.

Simple partial status most commonly involves focal motor seizures in the syndrome *epilepsia partialis continua* (actually a convulsive form of partial status). Neurological deficits occurring as the sole manifestation of simple partial non-convulsive status are rare and include ictal aphasia (Kirshner *et al.* 1995) and ictal blindness (Barry *et al.* 1985). Instances of simple partial status involving subjective experiential phenomena in the absence of impaired consciousness (sometimes called *aura continua*) are the most likely to be confused with psychiatric disorder. Fortunately, such presentations seem to be very uncommon. Well-documented case reports have included patients with protracted epigastric, olfactory and gustatory aura (Wieser *et al.* 1985; Manford & Shorvon 1992) lasting from 30 minutes to several days. Manford and Shorvon considered that longer durations were possible and that cases were more common in clinical practice than the scarcity of case reports would seem to suggest. Most recently, Seshia and McLachlan (2005) have suggested that subtle forms of simple partial status with elementary sensory aura may even continue for years. In a brief report, these authors describe six patients who had ongoing symptoms that were similar to, though less intense than, their usual aura and lasted for 2–8 years. Anxiety as the only manifestation of simple partial status has been reported by McLachlan and Blume (1980). These authors describe a 21-year-old woman with episodes of fear lasting up to 12 hours during which she remained fully alert. She also had nocturnal complex partial seizures. EEG recordings demonstrated rhythmic discharges in the right anterior temporal region during episodes of fear. The onset of an episode was not captured but on one occasion ictal symptoms and EEG abnormalities disappeared simultaneously. Complex sensory phenomena have also been described in simple partial status epilepticus. However, protracted complex experiential symptoms that are demonstrably epileptic in origin and which occur in clear consciousness are exceptionally rare. Wieser (1980) describes a young woman who experienced recurrent episodes of non-convulsive status during

depth-EEG recording. Two episodes began with protracted musical hallucinations in which the patient heard a familiar song (that was, however, different on each occasion) repeated over and over again. She was fully alert for at least 3 hours at the beginning of each episode, which thereafter evolved to complex partial status. The musical hallucinations were associated with a seizure discharge in right Heschl's gyrus. Consciousness became impaired as the discharge spread to involve medial temporal lobe structures bilaterally. There have also been single case reports of patients with episodes of complex visual (Sowa & Pituck 1989) and auditory (Blanke *et al.* 2003) hallucinations but both cases probably fall short of status because individual hallucinatory episodes were brief (minutes), albeit recurrent, and neurophysiological evidence of status was dubious.

Overall, it seems likely that our view of the clinical spectrum of non-convulsive status will broaden. Non-convulsive status should be suspected in any patient known to have epilepsy who presents with a protracted alteration in behaviour or mental state, especially if there is any suggestion of clouding of consciousness. On the current evidence it seems that epigastric aura and elementary sensory symptoms may sometimes occur in protracted form as simple partial status. However, when more complex psychiatric symptoms, including complex hallucinations, occur as protracted ictal phenomena it is almost always in the context of complex partial status, in which case clouding of consciousness and motor signs will suggest the correct diagnosis. EEG should be performed but a scalp recording is likely to be normal during simple partial status. In these cases a dramatic response to parenteral benzodiazepines supports, though does not prove, an epileptic aetiology.

Absence status. Absence status is a prolonged state of impaired consciousness associated with continuous 3-Hz spike-and-wave EEG abnormality (Shorvon & Walker 2005; Walker *et al.* 2005). It is usually seen in a child or adolescent known to have generalised epilepsy. The initial episode typically occurs a few years after epilepsy is first diagnosed but may occasionally be the first clinical presentation. Episodes are recurrent in over 80% of cases. Absence status has also recently been described in elderly patients, occurring either in patients with a history of generalised epilepsy or arising *de novo* in the context of metabolic disturbance and benzodiazepine withdrawal (Thomas *et al.* 1992; Agathonikou *et al.* 1998). The clinical features of absence status are sometimes surprisingly inconspicuous and the diagnosis may go unrecognised (Toone 1981; Shorvon & Walker 2005). Episodes usually start and stop abruptly, characteristically finishing with a tonic-clonic seizure or with sleep. They may last from several minutes to several hours or even days, during which the subject is confused, uncoordinated, slowed and perseverative. The degree of clouding of consciousness varies: at its slightest there is

simply slowing of ideation and expression, but more commonly there is marked disorientation, confusion and automatic behaviour. The patient may be virtually stuporose, remaining motionless and apathetic, but if partially aroused is usually capable of limited voluntary action and may sometimes even respond to simple commands. In contrast with complex partial status, cycling between different states of consciousness is not seen. Motor features, present in about half of cases, are bilateral and myoclonic, involving periocular and periorbital regions or the upper limbs. Eyelid myoclonus is a particularly valuable sign in differentiating absence from complex partial status. Sometimes environmental stimulation will interrupt the condition, both in its clinical and EEG manifestations (Landolt 1958). Subsequently, there is complete amnesia for the episode or only a blurred and fragmentary memory. Abnormal mental states other than clouding of consciousness are very uncommon. Early descriptions of psychotic states have not been confirmed in more recent series and probably represent cases of complex partial status that were misidentified as absence status (Toone 1981).

Postictal disorders

Delirium

While epileptic seizures characteristically begin abruptly, recovery of normal function is usually gradual. In a complex partial seizure the transition from a state of unresponsiveness and confusion to one of alertness typically takes place over minutes. To an observer the impression is not unlike that of someone coming slowly to their senses after being awoken from sleep. The patient slowly becomes aware of where he is and gradually interacts more appropriately. The duration of clouding of consciousness and automatisms is characteristically more prolonged in temporal lobe seizures, whereas recovery may be surprisingly abrupt following frontal lobe seizures. Consciousness is more profoundly impaired following a generalised tonic-clonic seizure and recovery more protracted. Typically, patients are alert and responsive within 15 minutes or so, although they will often complain of headache, drowsiness and mental slowing. Even when overt delirium resolves relatively quickly, it is quite common for patients to report that they do not feel fully restored to their normal selves in terms of mental function for a day or two after a tonic-clonic seizure. On occasions, full recovery of consciousness may take much longer, especially in the elderly or in patients with learning difficulties. In such cases the distinction between prolonged postictal delirium and non-convulsive status may be very difficult (Fagan & Lee 1990). In patients with an established history of epilepsy, any pronounced deviation from their habitual pattern of recovery will obviously raise concerns. Careful observation for motor signs is important and an EEG will usually clarify the diagnosis.

Psychosis

The term 'postictal psychosis' refers to brief self-limiting episodes of psychosis that are of abrupt onset and follow seizures. The syndrome has now been well described in a number of case series (Logsdail & Toone, 1988; Savard *et al.* 1991; Devinsky *et al.* 1995; Umbricht *et al.* 1995; Kanner *et al.* 1996; Alper *et al.* 2001).

Clinical features. Postictal psychosis is probably the most common psychotic disorder seen in epilepsy. Prevalence rates of around 6% have been reported in two telemetry series (Kanner *et al.* 1996; Alper *et al.* 2001). Most patients have TLE, but the disorder may occur in other localisation-related syndromes and in generalised epilepsy: 3 of 14 patients reported by Logsdail and Toone (1988) fell into the latter category. Epilepsy has usually been present for over 10 years before the first episode. The precipitating event is an exacerbation of seizures, usually either a cluster of complex partial seizures or a secondarily generalised seizure. This is characteristically followed by a lucid interval (Logsdail & Toone 1988), lasting up to 24 hours, during which the patient appears to recover fully from the after-effects of seizures. The onset of psychotic symptoms is then often sudden and dramatic, accompanied by marked agitation and behavioural disturbance. The phenomenology is pleomorphic with a mixed picture including paranoid, grandiose and religious delusions, auditory, visual and somatic hallucinations, and prominent variable affective changes. While some have reported intermittent delirium, it is important to emphasise that these are true psychotic disorders with psychotic symptoms occurring mainly in the absence of impaired consciousness. A representative estimate of the mean duration of the psychotic episode is 3.5 days, with a range from 16 hours to 18 days (Devinsky *et al.* 1995). EEG obtained during an episode of postictal psychosis may show diffuse background slowing or an increase in interictal epileptiform abnormalities (Logsdail & Toone 1988; So *et al.* 1990), changes that are typical of post-seizure recordings in general.

In clinical practice, postictal psychosis must be differentiated from non-convulsive status. In most cases the distinction will be straightforward. Periods of impaired consciousness and intermittent motor signs will help identify patients with ongoing partial seizures. However, there is some potential overlap. Psychotic symptoms, agitation and behavioural disturbance may feature in both disorders. Impaired consciousness points to a diagnosis of status but subtle degrees of clouded consciousness may be impossible to exclude in a severely agitated psychotic patient. Furthermore, intermittent delirium is said to be a feature in some individuals with postictal psychosis. In this situation, the occurrence of a lucid interval is particularly helpful. In most cases of postictal psychosis, careful history-taking from an informant will establish a period of normal functioning between termination of seizure activity and psychosis.

As the episodes are self-limiting, treatment with antipsychotic medication is usually not indicated. However, the degree of agitation and behavioural disturbance may be such that hospital admission and sedation with benzodiazepines are required. Postictal psychoses have a tendency to recur and repeated episodes are often relatively stereotyped (Tarulli *et al.* 2001). Between 14% and 20% of patients with postictal psychosis will eventually develop chronic interictal psychoses, often after several years and recurrent episodes of postictal psychosis (Logsdail & Toone 1988; Tarulli *et al.* 2001). In the majority of such cases, Tarulli *et al.* found that the phenomenology of the chronic psychoses contained elements seen in preceding episodes of postictal psychosis. It is often stated that the main focus of treatment should be improved seizure control. In practice, however, this may be difficult. Most patients with postictal psychosis have epilepsy that has already proved unresponsive to several antiepileptic drugs. In those with TLE, the possibility of surgical treatment will often arise. However, postictal psychosis is strongly associated with bilateral temporal lobe pathology (see below), which must be carefully excluded before proceeding to lobectomy. There is a potential role for neuroleptics in preventing recurrent episodes of postictal psychosis and even reducing the risk of progression to chronic psychosis. Unfortunately, there is no evidence on which to base decisions about such treatment.

Risk factors. In a case-control study of psychiatric risk factors, Alper *et al.* (2001) found the only factor associated with postictal psychosis to be a family history of affective disorder. With regard to neurological variables, patients with postictal psychosis tend to have more frequent seizure clustering and secondary generalisation (Devinsky *et al.* 1995; Umbricht *et al.* 1995). Among those with TLE, the most consistent finding has been an association with bilateral temporal lobe pathology: bilateral EEG abnormalities are over-represented, as are aetiologies that are associated with diffuse damage such as encephalitis and head injury. These findings have emerged from case series (Logsdail & Toone 1988; Savard *et al.* 1991), case-control studies (Devinsky *et al.* 1995; Umbricht *et al.* 1995) and also from case reports of a small but interesting subgroup of patients who first develop postictal psychosis after temporal lobectomy (Manchanda *et al.* 1993; Christodoulou *et al.* 2002). Christodoulou *et al.* (2002) report three such patients, all of whom had postoperative seizures arising from either the side contralateral to the operation (two cases) or bilaterally (one case). These three patients represented 5.5% of those with postoperative seizures, but one-third of those (nine patients in total) who developed contralateral or bilateral postoperative seizures. In patients being considered for temporal lobe surgery, a history of postictal psychosis should therefore raise a strong suspicion of bilateral pathology.

Finally, Briellmann *et al.* (2000) have reported quantitative MRI and histopathological findings in 51 patients with refractory TLE, six of whom had postictal psychosis. Postictal psychosis was associated with a relative preservation of anterior hippocampal volume and more frequent temporal lobe dysplasia. Bilateral abnormalities were not noted in this series but all patients were undergoing presurgical work-up and this may have led to a selection bias favouring those with unilateral disease.

In summary, postictal psychoses are the most common form of psychosis in patients with epilepsy. The clinical presentation is distinctive, with a sudden onset of mixed psychotic and affective features, most notably agitation, following a brief lucid interval after seizures. Individual episodes resolve within days but they tend to recur and a significant minority of patients will eventually develop chronic interictal psychoses. Postictal psychosis occurs most frequently in patients with TLE in whom the syndrome is associated with bilateral temporal lobe pathology. The pathophysiology of postictal psychosis is not understood but it is distinct, on clinical and electrophysiological grounds, from non-convulsive status. Postictal psychosis presumably reflects some transient physiological disturbance superimposed on a substrate of epileptogenic abnormality.

Interictal disorders

Depression

Depression and anxiety are the most frequently encountered interictal psychiatric disorders in epilepsy (Lambert & Robertson 1999; Harden 2002; Kanner 2003). However, exactly how common they are remains uncertain. Estimates of the prevalence and incidence of depression in epilepsy have varied up to tenfold. A familiar list of methodological considerations, especially those relating to sample characteristics and case definition, account for this variability. Community-based studies have found symptoms of depression (as distinct from depressive disorder) in 4–37% of people with epilepsy (Edeh & Toone 1987; Jacoby *et al.* 1996; O'Donoghue *et al.* 1999; Ettinger *et al.* 2004). Of the many studies that have investigated depression in patients attending specialist clinics, those that have used ICD or *Diagnostic and Statistical Manual of Mental Disorders* (DSM) diagnostic criteria are most easily interpreted. The prevalence of major depression in such settings has been estimated as 17–21% (Brookes & Crawford 2002; Jones *et al.* 2005). Further studies have examined patients with epilepsy admitted for presurgical evaluation. Such samples are of course highly selected, with the overwhelming majority of patients having medically refractory TLE. In these patient groups the lifetime prevalence of depression meeting DSM criteria has been estimated at 24–35% (Victoroff *et al.* 1994; Altshuler *et al.* 1999;

Glosser *et al.* 2000). Estimates of the point prevalence of DSM major depression in similar series have ranged from 3% over the past month (Manchanda *et al.* 1996) to 22% over the previous year (Devinsky *et al.* 2005). Bipolar disorder does not appear to be over-represented in epilepsy: even in presurgical series prevalence rates of below 1% are reported.

Relatively few studies have compared the prevalence of depression in epilepsy with other medical disorders. Most have used symptom measures rather than case definitions of depression. Mendez *et al.* (1986) sent postal questionnaires to individuals presenting to vocational services for the disabled. People with epilepsy reported more depressive symptoms than those with other disabilities despite similar ratings of disability. Two studies have reported higher rates of depression in patients attending specialist epilepsy centres compared with controls with insulin-dependent diabetes (Perini *et al.* 1996; Beghi *et al.* 2002). A further study found higher rates of depression in epilepsy compared with a mixed group of neurological disorders (Kogeorgos *et al.* 1982). Ettinger *et al.* (2004) conducted a large postal survey comparing the prevalence of depressive symptoms in people with epilepsy, asthma and controls. Symptoms of depression were most commonly reported by those with epilepsy, but differences between the epilepsy and asthma groups fell short of statistical significance when demographic variables were taken into account. Using similar survey methods, the same investigators have reported higher rates of bipolar symptoms (as distinct from bipolar disorder) in people with epilepsy compared with various medical control groups (Ettinger *et al.* 2005). Although half of those with bipolar symptoms reported being given a past diagnosis of bipolar disorder, it is possible that these findings reflect atypical forms of depression that some authorities have said are common.

Clinical presentation of depression in epilepsy

The possibility that depression in epilepsy may take atypical forms has attracted considerable interest. Several investigators have been struck by the fact that depressive symptoms in people with epilepsy often fall short of standard diagnostic criteria and yet are associated with significant morbidity (Mendez *et al.* 1986; Glosser *et al.* 2000). The terms 'interictal dysphoric disorder' (Blumer 1991) and 'dysthymia-like disorder of epilepsy' (Kanner 2003) have been proposed to describe these presentations. Essentially, the clinical picture is one of chronic dysthymia which is interrupted at frequent intervals by brief periods of normal mood. Affective symptoms are pleomorphic, with prominent irritability and endogenous somatic symptoms. Patients would meet standard diagnostic criteria for chronic dysthymia were it not for the intermittent course of the disorder (Kanner 2003). Blumer (1991) has described a more elaborate complex of symptoms including labile depressive symptoms (depressed

mood, with somatic symptoms including anergia, insomnia and pain), other affective symptoms (anxiety and phobias) and 'specific symptoms' of paroxysmal irritability and brief episodes of euphoric mood. It has been suggested that 30–70% of patients with epilepsy and depression have these atypical features. The syndrome is said to respond to antidepressant treatment perhaps in combination with low-dose neuroleptics (Blumer *et al.* 1995). Most clinicians will recall patients who seem to fit these descriptions but much work needs to be done to establish the validity of the concept. In particular, phenomenological comparisons with the spectrum of affective presentations in people without epilepsy are required to establish whether the syndrome is truly specific to epilepsy. The atypical nature of these presentations is cited as one reason why depression in epilepsy often goes unrecognised and untreated. Controlled trials demonstrating that such symptoms respond to treatment would help support the assertion that patients with atypical presentations represent a significant unmet need.

Risk factors for depression

A relationship between depression and poorly controlled epilepsy was most clearly demonstrated in the community-based study by Jacoby *et al.* (1996) already referred to in this chapter. Information on 696 patients was collected from general practice records and by postal questionnaires. Around half of the patients had been free of seizures for over a year, 27% were experiencing one or less seizures per month and 20% had more frequent seizures. Among seizure-free patients, 4% were found to have significant depression scores on the Hospital Anxiety and Depression Scale. The figure rose to 10% in those experiencing less than one seizure per month and to 21% in those with more frequent seizures. O'Donoghue *et al.* (1999) replicated these findings in their study: corresponding figures for depression in the three groups were 6% (seizure-free group), 11% (less than one seizure per month) and 33% (greater than one seizure per month). Studies based in tertiary referral centres are naturally biased in favour of patients with poorly controlled epilepsy. In these settings, a relationship with seizure frequency is generally not found (Mendez *et al.* 1986; Altshuler *et al.* 1999). However, when such patients undergo temporal lobectomy, becoming seizure-free is associated with an improvement in depressive symptoms (Reuber *et al.* 2004; Devinsky *et al.* 2005).

Depression is often believed to be especially common in patients with TLE (Lambert & Robertson 1999). This view has found some support from direct comparisons between epilepsy syndromes. Thus, Perini *et al.* (1996) identified depression in 11 of 20 patients with TLE, compared with 3 of 18 patients with JME. A larger study comparing 150 patients with localisation-related epilepsy and 70 with idiopathic generalised epilepsy found higher measures of depression

and anxiety in the former group (Piazzini & Canger 2001). However, the mean seizure frequency in those with generalised epilepsy was less than one per year, while those with partial seizures averaged six per month. This was not controlled for in the analyses and may well have confounded the results. In contrast, a number of recent studies have found similar rates of depression across epilepsy syndromes (Manchanda *et al.* 1996; Beghi & Cornaggia 2002; Wrench *et al.* 2004; Jones *et al.* 2005). For example, Jones *et al.* (2005) found no relationship between major depressive disorder and epilepsy syndrome among 174 outpatients with chronic epilepsy, 55% of whom had localisation-related and 41% idiopathic generalised epilepsy. Underlining the fact that patients with generalised epilepsy are at risk of depression, Cutting *et al.* (2001) have described a series of 42 patients with adult-onset idiopathic generalised epilepsy. Overall, outcome was favourable, with seizures completely controlled in two-thirds and 90% in full employment. Despite this, one-quarter of these patients had a history of depression.

Flor-Henry (1969) originally suggested that depression, particularly depressive psychosis, was associated with right-sided TLE. Subsequent findings have been inconclusive, if anything marginally in favour of an association with left-sided TLE (Lambert & Robertson 1999). Recent temporal lobectomy series have cast further doubt on the issue: most, including the largest series published to date (Devinsky *et al.* 2005), have found no relationship with laterality (Ring *et al.* 1998; Altshuler *et al.* 1999); others have reported differences favouring an association with left-sided pathology (Quigg *et al.* 2003) or right-sided pathology (Glosser *et al.* 2000). If there is an effect of laterality on depression in epilepsy, it must surely be a small one.

No consistent relationships have emerged for other demographic and epilepsy-related variables including age, gender, age of onset or duration of epilepsy. A family history of psychiatric illness was found in 50% of patients with epilepsy and depression by Robertson *et al.* (1987) but Mendez *et al.* (1986) found that such a family history was less common in patients with depression and epilepsy than in a non-epileptic depressed control group. Adverse psychiatric reactions are well recognised with a number of antiepileptic drugs (Schmitz 1999). In most cases symptoms are mild, comprising non-specific features such as dysphoria, irritability and anxiety. More severe reactions, including psychosis, are less common. There are limited data concerning newer antiepileptic drugs but these 'neurobehavioural' symptoms are now routinely reported in preclinical trials. Often, however, the extent to which a particular drug is associated with adverse effects is not clear until it has been in clinical use for several years. No drug can be said to be free of adverse psychiatric effects. Those most frequently implicated include levetiracetam, tiagabine, topiramate and vigabatrin. Folic acid depletion may be caused by antiepileptic drugs, especially by those that induce hepatic enzymes, and

is a treatable cause of depression (Froscher *et al.* 1995). Overall, temporal lobectomy is associated with a reduction in psychiatric morbidity, especially when seizures are abolished. However, approximately one-third of patients will suffer a short-lived episode of depression, typically accompanied by anxiety, and emotional lability arising *de novo* a few weeks after their operation (Ring *et al.* 1998; Wrench *et al.* 2004). Those with a history of depression are at greatest risk but these reactions may occur in the absence of a past psychiatric history. Early recognition and treatment are important as symptoms may be severe, with a risk of suicide. On current evidence the natural history of these disorders seems to be for resolution within 6 months or so. These episodes may be more common after right-sided temporal lobectomies, and are less frequent following surgery for FLE. They are equally likely to occur in those with and without seizure recurrence and appear to be a biological consequence of temporal lobe surgery.

Overall, depression is undoubtedly common in people with epilepsy, especially those with poorly controlled seizures attending specialist services. Patients with TLE are particularly likely to fall into this category. However, earlier impressions of a specific association with TLE, and with right- or left-sided pathology, have not been substantiated. Depression may arise as a direct consequence of medical and surgical treatment. For most patients, however, psychosocial factors related to poorly controlled epilepsy are undoubtedly important. Ongoing seizures are associated with far-reaching effects on people's lives. In addition to the practical consequences of disability, including unemployment, dependence, social limitations and driving restrictions, epilepsy is still a stigmatised disorder. People whose epilepsy is in remission have a quality of life that is no different from the general population. They are also at no substantially increased risk of depression. For those with ongoing seizures, depression is the single most important predictor of a poor quality of life (Boylan *et al.* 2004). Freedom from seizures must clearly be the aim of epilepsy treatment, and the recognition and treatment of depression must be a high priority for all those involved in caring for people with epilepsy.

Anxiety

Anxiety arising as a direct manifestation of an epileptic discharge has been discussed in the preceding section on ictal psychiatric symptoms. In relation to interictal psychiatric disorders, anxiety and depression are probably equally common. Many studies have in fact found slightly higher rates of anxiety symptoms (Jacoby *et al.* 1996; Manchanda *et al.* 1996; O'Donoghue *et al.* 1999; Jones *et al.* 2005). Risk factors for anxiety have received far less attention but there is clearly considerable overlap with depression. Certainly, the relationship between anxiety and the presence of ongoing

seizures is exactly the same as for depression (Jacoby *et al.* 1996; O'Donoghue *et al.* 1999).

The most frequent diagnoses are agoraphobia, generalised anxiety disorder and social phobia (Jones *et al.* 2005). Obsessive-compulsive disorder is not over-represented in epilepsy. The term 'seizure phobia' is sometimes used to refer to the situation in which a patient's fear of having a seizure is more disabling than the seizures themselves. The fear may be one of injury or embarrassment and is disproportionate to objective risk. The clinical picture has much in common with agoraphobia, patients engaging in a range of safety and avoidant behaviours that maintain their anxiety. Striking examples are sometimes encountered in patients who have had a successful outcome following epilepsy surgery. Despite becoming free of seizures such patients may remain virtually housebound through fear of having a seizure which, of course, becomes increasingly irrational as the period of seizure freedom extends. Such cases represent an archetypal paradigm for the role of avoidance in perpetuating phobia and respond well to cognitive-behaviour treatment. The situation may be more complex in the presence of ongoing seizures. Entrenched beliefs about epilepsy and what it means to be 'epileptic' may foster highly charged reactions of horror and disgust to seizures. In relation to the likelihood of injury, the boundaries between maladaptive safety behaviour and calculated risk-taking may be difficult to define. The clinical picture may be further complicated by benzodiazepine dependence. Benzodiazepines prescribed as rescue medication for prolonged seizures are likely to be taken inappropriately, either in response to supposed prodromal symptoms (for which the patient becomes increasingly vigilant) or as self-medication for anxiety. Newsom-Davis *et al.* (1998) give a detailed description of the application of cognitive-behaviour therapy in such a case.

Epilepsy and suicide

The risk of suicide is higher in people with epilepsy compared with that in the general population. However, reported rates of suicide have varied considerably between studies depending on the characteristics of the patient populations being considered. In an early review Barraclough (1981) concluded that epilepsy was associated with a fivefold increased risk of suicide, but noted that a 25-fold increase had been described in some highly selected samples. In contrast, two population-based studies of mortality in epilepsy have found no increased risk (Hauser *et al.* 1980; Cockerel *et al.* 1994). Most recently, in a careful cohort study involving over 9000 patients who had been admitted to hospital at one stage for epilepsy, Nilsson *et al.* (1997) reported a standardised mortality ratio for suicide of 3.5.

By far the most important risk factors for completed suicide in epilepsy are psychiatric history and previous suicide attempts. In this, patients with epilepsy who take their own lives are no different from other cases of suicide.

Obviously this highlights the importance of identifying psychiatric disorder in people with epilepsy. Of particular interest, however, is whether any specific clinical aspects of epilepsy are associated with greater risk. This question has been addressed in a careful case-control study reported by Nilsson *et al.* (2002). These authors compared psychiatric and neurological variables in 49 patients with epilepsy who had committed suicide (or probable suicide) and 171 epilepsy controls. A psychiatric history was associated with a ninefold risk of suicide. Less expectedly, early-onset epilepsy, especially epilepsy beginning during adolescence, was an important risk factor. The estimated relative risk of suicide was 16 (95% CI 4.4–58.3) for onset of epilepsy before 18 years of age, compared with onset after 29 years. There was a trend for patients with more frequent seizures and for those taking multiple antiepileptic drugs to be at increased risk but this fell short of significance. Incomplete neurological clinical records were more common in the cases of suicide, which led the authors to speculate that inadequate neurological follow-up, perhaps through non-attendance, could be a contributory factor. No relationship emerged between suicide and a range of other epilepsy-related variables, including type of epilepsy, localisation or lateralisation of the epileptogenic focus, the presence of neurological deficit or any specific antiepileptic medication.

Schizophrenia-like psychosis

The interictal schizophrenia-like psychoses of epilepsy are psychotic disorders that would meet diagnostic criteria for schizophrenia were it not for the coexistence of epilepsy. Implicit in this definition is that the psychotic episodes are of relatively long duration and show either no, or a variable, relationship to the occurrence of individual seizures.

Most early studies reported an excess of schizophrenia-like psychosis in people with epilepsy (see reviews by Sachdev 1998; Lancman 1999). A study by Mendez *et al.* (1993a) is noteworthy because it included a control group and used standard diagnostic criteria. These authors compared the prevalence of psychosis among 1611 patients attending an epilepsy clinic and 2167 patients attending a migraine clinic. A history of psychosis was found in 9.25% of the epilepsy group and 1.06% of the migraine patients. The prevalence of more narrowly defined schizophrenia in the epilepsy group was 4.72% once cases meeting DSM-III-R criteria for schizoaffective or undifferentiated psychosis were excluded. More recently, two epidemiological studies have provided support for the association. Stefansson *et al.* (1998) reported the prevalence of ICD-9 psychiatric diagnoses among disability claimants in Iceland, comparing 241 patients with epilepsy (patients with learning disability were excluded) and 482 subjects with non-neurological causes of disability. The overall prevalence of psychiatric disorder was similar in the two groups (35% and 30%, respectively) but schizophrenia and paranoid psychosis were significantly

more common in the epilepsy group (3% compared with 0.6%). However, the most convincing evidence comes from a study of the Danish population registers (Qin *et al.* 2005). These authors examined the health registers for 2.7 million people born between 1950 and 1987, including data gathered up until 2002. ICD definitions of schizophrenia and epilepsy were used. The relative risk of schizophrenia in individuals with a history of epilepsy was 2.48 (95% CI 2.20–2.80). The relative risk for non-affective psychosis, including schizophrenia, was 2.93 (95% CI 2.69–3.20). As impressive as these findings are, one caveat should be noted. Cases of epilepsy were identified by hospital admission records, raising a question about the extent to which these findings might apply overall to individuals with epilepsy. The authors argue that their figures are representative as, they say, over 80% of patients with new-onset epilepsy are admitted to hospital in Denmark and prevalence rates for epilepsy derived from their data are similar to those from other large epidemiological studies.

It is therefore now reasonable to conclude that epilepsy is indeed associated with an increased risk of schizophrenia. The evidence for this association is most robust for patients who have chronic epilepsy associated with significant disability or requiring specialist medical attention. Patients in this group are two to three times more likely to develop schizophrenia than the general population.

Nature of the psychosis

The modern era of our understanding of the epileptic psychoses began with the influential study by Slater *et al.* (1963) who described 69 patients with epilepsy and a diagnosis of schizophrenia. This remains the most detailed description of a large series of such patients. Their observations rested essentially on clinical judgement. The mean age of onset of schizophrenia was 30 after a mean duration of epilepsy of 14 years. All the cardinal symptoms of schizophrenia were exhibited and Slater *et al.* stressed that it would not be possible to diagnose these patients, on psychiatric symptomatology alone, as suffering from anything other than a schizophrenic psychosis. However, they noted that certain combinations of symptoms differed slightly from the usual schizophrenic patterns. Personality abnormalities before the onset of psychosis were not prominent. Catatonic phenomena were rare and the loss of affective response did not occur so early or become so marked as in primary schizophrenia. They commented that by and large the patients were friendlier, more cooperative and less suspicious towards hospital staff.

Subsequent reports have confirmed an interval of approximately 10–15 years between the onset of epilepsy and psychosis. However, the subtle phenomenological differences observed by Slater *et al.* have not been replicated. Although Kristensen and Sindrup (1979) commented on retention of affective warmth, neither Perez and Trimble (1980) nor Toone

et al. (1982) were able to demonstrate any significant distinguishing phenomenological features using objective symptom measures. Likewise, although Toone *et al.* (1982) found that psychotic epileptic patients tended to have less premorbid personality abnormality, this was not confirmed by Mendez *et al.* (1993a) who compared 62 psychotic epileptics with 62 age- and gender-matched schizophrenic controls.

Nearly half of Slater *et al.*'s series had a chronic course. When the onset had been acute the prognosis was better, sometimes with improvement to the point of recovery. Those with an episodic onset sometimes pursued a fluctuating course thereafter. Follow-up at a mean interval of 8 years from onset showed that one-third had achieved remission, and a further third had improved with regard to psychotic manifestations. Onuma *et al.* (1991) found that 64% followed a chronic course over a 10-year period. Toone *et al.* (1982) found little difference between outcome in their series of 69 patients who had been admitted to hospital with psychosis and epilepsy compared with 53 non-epileptic consecutive admissions matched for ICD diagnosis. Their epileptic patients had slightly more frequent and longer admissions and were more likely to have their diagnosis changed over time.

Risk factors

A considerable amount of research has focused on risk factors for developing schizophrenia-like psychosis in epilepsy. The most consistent finding has been an association between psychosis and various indices of epilepsy severity, including seizure frequency, measures of seizure severity, multiple seizure types, a history of status, and the number of epilepsy-related hospital admissions (Mendez *et al.* 1993a; Schmitz *et al.* 1999; Adachi *et al.* 2000; Qin *et al.* 2005).

No consistent relationship has emerged between psychosis and age at onset of epilepsy, with some studies finding younger age of onset of epilepsy to be a risk factor (Umbricht *et al.* 1995; Adachi *et al.* 2000) and others reporting a significant relationship with later age at onset of epilepsy (Mendez *et al.* 1993a). Qin *et al.* (2005) demonstrated that the risk of psychosis increased linearly with increasing age at first admission for epilepsy.

Slater *et al.* noted a preponderance of patients with TLE in their series and an association between localisation-related epilepsy and psychosis has been reported by most large case-control studies (Mendez *et al.* 1993a; Adachi *et al.* 2000), although there have been negative findings (Schmitz *et al.* 1999). However, given that seizures are more likely to be medically intractable in localisation-related epilepsy than in idiopathic generalised epilepsy, on the present evidence it is not possible to distinguish between the effect of epilepsy syndrome and severity. Furthermore, in the epidemiological study by Qin *et al.* (2005), patients with localisation-related epilepsy were only slightly over-represented among those

who were psychotic and this difference fell short of statistical significance. Related to the question of an association between type of epilepsy and psychosis, three studies have reported an increased rate of experiential epileptic auras among psychotic epileptics (Kristensen & Sindrup 1978a; Mendez *et al.* 1993a; Schmitz *et al.* 1999).

Perhaps the most controversial findings concern the relationship between psychosis and laterality of epileptic focus. Flor-Henry (1969) reported that among psychotic temporal lobe epileptics, those with schizophrenia were more likely to have dominant rather than non-dominant epileptic foci. Although this finding has received some support (Taylor 1975; Sherwin 1981; Perez *et al.* 1985), most findings have been negative (Kristensen & Sindrup 1978b; Jensen & Larsen 1979a; Umbricht *et al.* 1995; Schmitz *et al.* 1999). Most persuasively, two large case-control series have found no relationship between psychosis and the laterality of EEG abnormalities (Mendez *et al.* 1993a; Adachi *et al.* 2000). Functional neuroimaging studies have been divided, with evidence of both lateralised temporal lobe and more generally distributed abnormalities. Positron emission tomography (PET) in a small series revealed indications of reduced metabolism, especially in frontal, temporal and basal ganglia regions (Gallhofer *et al.* 1985). Marshall *et al.* (1993), in a small pilot study, obtained evidence from SPECT of lowered cerebral blood flow in the left medial temporal region in psychotic epileptic patients, and also in both thalami. In a larger SPECT investigation, Mellers *et al.* (1998) observed a significant *decrease* in blood flow in the left superior temporal gyrus during verbal activation, in contrast to non-psychotic epileptics and non-epileptic schizophrenic controls.

Structural imaging studies have found no consistent association with either regional or lateralised brain abnormalities. While Marchetti *et al.* (2003) found that left hippocampal volumes were smaller in 36 patients with epilepsy and psychosis compared with healthy (non-epileptic) controls, three studies have reported no differences in hippocampal volume between psychotic epileptics and epilepsy controls (Maier *et al.* 2000; Marsh *et al.* 2001; Tebartz van Elst *et al.* 2002). Instead, psychosis in epilepsy has been associated with a global reduction in cerebral volume (Marsh *et al.* 2001; Tebartz van Elst *et al.* 2002). The view that widespread cerebral damage rather than regional abnormality is relevant finds support from a number of other sources. Kristensen and Sindrup (1978a,b, 1979) reached this conclusion after they found that patients with epilepsy and psychosis were more likely to have generalised or multifocal EEG abnormalities, have a history of CNS insult, demonstrate abnormal neurological signs and have lower IQ measures than non-psychotic epilepsy controls. Umbricht *et al.* (1995) also found lower IQ measures in psychotic epileptics. Mellers *et al.* (2000) found that patients with schizophrenia-like psychosis of epilepsy showed an almost identical pattern of neuropsychological deficits compared with a matched group of patients with

schizophrenia, with evidence of memory and executive impairments on a background of attentional and IQ deficits that suggested global cerebral dysfunction. Finally, in the only post-mortem study so far, Bruton *et al.* (1994) compared 19 patients with epilepsy and psychosis with 36 non-psychotic epilepsy controls. TLE and mesial temporal sclerosis occurred with equal frequency in the psychotic and control subjects. The psychotic group were distinguished from the controls by the presence of distributed cerebral pathology. The pathological findings included increased ventricular size, periventricular gliosis, more focal brain abnormalities and perivascular white-matter softening.

An additional finding is that where patients with schizophrenia-like psychoses have come to temporal lobectomy, mesial temporal lobe sclerosis has seemed less common than in TLE generally, and small cryptic tumours (hamartomas) have been particularly common (Taylor 1972; Falconer 1973). Taylor (1975) compared 47 patients whose resected specimens showed 'alien tissue' (small tumours, hamartomas and focal dysplasia) with 41 showing mesial sclerosis; 23% of the former but only 5% of the latter had been psychotic. In contrast, Roberts *et al.* (1990), in a further analysis of the material, found that mesial sclerosis was not uncommon in the presence of a schizophrenia-like psychosis but a second form of pathology (alien tissue ganglioglioma) was significantly more common in those who developed psychoses postoperatively. The lesions arise early in fetal or neonatal life and were associated with a particularly early onset of seizures. Where lesions were found in the resected specimens from patients with schizophrenia-like psychoses, they always involved the medial temporal lobe structures (amygdala, hippocampus and parahippocampal gyrus), the lateral parts of the lobe being rarely affected. Shaw *et al.* (2004) examined a further series of 11 patients with postoperative schizophrenia-like psychosis, comparing them to 33 postoperative non-psychotic controls. In agreement with the above findings, lesions other than mesial temporal sclerosis were over-represented in the psychotic group. Other risk factors were bilateral (preoperative) EEG abnormalities and a smaller amygdala on the unoperated side. Onset of psychosis was typically within 1 year of the operation, suggesting that the operation may have acted as a trigger for psychosis in vulnerable individuals.

A marked effect of left-handedness was seen in Taylor's patients (described above), 7 of 13 psychotic patients being left-handed compared with only 11 of 75 non-psychotic patients. In the alien tissue group, females, particularly left-handed females, were especially likely to have developed a schizophrenia-like psychosis. However, neither gender (Qin *et al.* 2005) nor left-handedness (Oyebode & Davison 1990) have been implicated as risk factors in other studies.

Finally, a number of authors have investigated family history of psychosis as a risk factor. Unfortunately, none of these studies have used a formal family interview approach.

Compared with epilepsy controls, patients with psychosis and epilepsy have an increased rate of family history of psychiatric disorder (Jensen & Larsen 1979b; Adachi *et al.* 2000). Compared with patients who have schizophrenia, psychotic epileptics have been reported as having similar (Toone *et al.* 1982) or less (Mendez *et al.* 1993a) family psychiatric history. Qin *et al.* (2005) examined the medical database for first-degree relatives of cases identified in their epidemiological study. They concluded that a family history of psychosis contributed to the risk of psychosis among patients with epilepsy and that the effect of a personal history of epilepsy on the risk of psychosis was greatest in those without a family psychiatric history. Interestingly, they also found that a family history of epilepsy was associated with a small but significant increased risk of psychosis.

Aetiology

Mechanisms behind the association between epilepsy and chronic schizophrenia-like psychoses have been considered in some detail (Symonds 1962; Slater *et al.* 1963; Sachdev 1998). Chance association may be operative, or precipitation in individuals genetically predisposed to schizophrenia. The psychosocial burden imposed by epilepsy or the effects of antiepileptic drug treatment may be important. Or there may be more direct links of a physiological nature.

A merely chance association appears unlikely. There is now robust evidence that intractable epilepsy is associated with a twofold to threefold increased risk of schizophrenia. However, it should be noted that if this figure is correct, then given the prevalence of schizophrenia, up to one in two patients with schizophrenia and epilepsy do have the two disorders by chance coincidence alone. This constitutes an important methodological problem for any investigation of specific aetiological links between epilepsy variables and psychosis.

Precipitation in individuals genetically predisposed to schizophrenia similarly appears unlikely to account for most cases. Patients with psychosis and epilepsy probably have a genetic diathesis for psychosis that lies between that found in the general population (and non-psychotic patients with epilepsy) and that found in patients with schizophrenia. Qin *et al.* (2005) have shown that a personal history of epilepsy increases the risk of schizophrenia in the absence of a family history of psychosis.

An increased risk of schizophrenia is best established for individuals who suffer from intractable and disabling epilepsy. However, disability alone does not appear to account for the increased incidence of psychosis. Stefansson *et al.*'s (1998) comparison of disability claimants with epilepsy and a group of non-neurological disability claimants found similar rates of psychiatric morbidity in the two groups but an increased risk of psychosis in the epilepsy group alone.

Psychosis has been reported as a rare complication of treatment with nearly every antiepileptic drug (Schmitz 1999). However, such psychoses usually resolve once the offending

drug is withdrawn. Drug effects alone therefore seem unlikely to account for the recurrent or chronic psychoses most commonly associated with epilepsy. Furthermore, specific drugs have not been implicated in case-control studies (Mendez *et al.* 1993a). In a consecutive series of 44 patients with epilepsy and a variety of psychoses, Matsuura (1999) noted seven (16%) that followed the introduction of an add-on antiepileptic drug. In most cases the drug appeared to act as a trigger for psychosis in patients with a history of recurrent psychotic episodes. In some patients, notably in children treated with ethosuxamide, the appearance of psychosis may coincide with cessation of seizures (*alternative psychosis*) and the loss of paroxysmal abnormalities on EEG (*forced normalisation*) (Krishnamoorthy & Trimble, 1999). Thus, while epilepsy and psychosis are associated, within this association, at least in some individuals, there appears to be a biological antagonism between seizures and psychosis.

Overall, the evidence favours direct aetiological links between epilepsy (or its attendant brain dysfunction) and psychosis. The latter may be viewed as a 'symptomatic schizophrenia' analogous to that emerging with other brain lesions or with amphetamine abuse. The aetiological link with epilepsy could be via the seizures themselves, or by way of the underlying disorder of cerebral function that manifests itself as epilepsy.

Favouring the view that seizure activity might be important is the observation that epilepsy has usually been present for many years before the psychosis supervenes, also that various indices of seizure severity are associated with psychosis. The link between seizures and psychosis is most compelling in the case of the postictal psychoses (see Postictal disorders, earlier), in which there is, by definition, a clear temporal relationship between seizures or seizure clusters and psychotic symptoms. Furthermore, some 15% of patients with postictal psychosis will eventually develop chronic interictal psychosis (Tarulli *et al.* 2001), supporting the notion that seizure-related mechanisms have a role in the latter group.

Evidence that the underlying brain pathology or dysfunction is of primary importance stems from observations made regarding psychosis in patients undergoing temporal lobectomy (Taylor 1972; Roberts *et al.* 1990; Shaw *et al.* 2004). Patients who are psychotic before operation are likely to remain so, whether they become seizure-free or not. Of equal interest, patients may develop psychosis for the first time after the operation and, again, this may happen regardless of whether the operation successfully halted seizures. These observations suggest that factors related to epilepsy, but independent of the occurrence of seizures, are important. Possible factors in this category include pathological abnormalities of a developmental origin mentioned above and the functional burden imposed by distributed cerebral structural abnormalities that have been identified by neuroimaging and neuropathological studies.

A number of authors have speculated about possible psychological links between experiences during seizures and psychosis. The patients in Slater *et al.*'s series had often experienced complex aura symptoms, and a number explained them in a delusional way; the symptoms in fact came to enter into the content of the delusional psychoses. Pond (1962) suggested that there may sometimes be a causal relationship of a psychological kind between seizures and psychosis, the latter arising from abnormal emotional experiences, physically caused, which then become integrated into the totality of psychic life as a psychodynamic process. However, there are difficulties in accepting such a mechanism as a general explanation. Although some studies have reported an association between epileptic aura and psychosis, a substantial proportion of psychotic epileptics have generalised epilepsy and therefore do not experience auras. Furthermore, while a psychological explanation might be plausible for the derivation of delusional symptoms, or at least their content, it would be hard to account for psychotic features such as hallucinations, thought disorder or volitional disturbance on such a basis.

A physiological formulation of the link was put forward by Symonds (1962). In this view, both the epilepsy and the psychosis are manifestations of the same basic disorder of cerebral function within the temporal lobes, the epilepsy being an earlier and intermittent manifestation, and the psychosis a later product. Symonds postulated that this abnormality might consist not so much of the static lesion responsible for the epilepsy, but rather of the disordered electrophysiological activity which spreads within the temporolimbic system. At peaks of such disorder seizures are likely to occur, but the background disturbance may persist between attacks, with far-reaching effects on psychological function. In effect Symonds suggested that

the temporal lobe includes within its boundaries circuits concerned with the physiological basis of the psychological disorder we call schizophrenia . . . it is not the loss of neurones in the temporal lobe that is responsible for the psychosis, but the disorderly activity of those that remain.

Stevens (1992) put forward a not dissimilar formulation. Brain damage is known to provoke regenerative sprouting of axons and synaptic proliferation, even in adults, and resected specimens from patients with TLE have shown sprouting of cells in the dentate gyrus and expansion of postsynaptic receptor sites in the parahippocampal gyrus. The functional consequences of such changes are largely unknown, but reorganisation of this nature, as a consequence of insults from seizures, could be associated with the onset of schizophrenia.

In summary, patients with intractable epilepsy have a twofold to threefold increased risk of schizophrenia. Psy-

chotic symptoms typically begin some 15 years after the onset of epilepsy. Early observations suggesting subtle phenomenological differences between these psychoses and primary schizophrenia have not been confirmed. The prognosis is similar to primary schizophrenia. A family history of psychosis is a risk factor but a direct aetiological link between epilepsy and psychosis is likely to account for most cases. There is evidence to suggest that this link may be mediated through cumulative effects of recurrent seizures and by static effects of underlying brain pathology. Thus, patients with frequent severe seizures associated with distributed cerebral dysfunction and structural change are at greatest risk. A close association with TLE and with left-sided seizure foci now seems less likely. Certain pathological lesions originating early in neurodevelopment may be over-represented.

Personality in epilepsy

The notion that epilepsy might be associated with specific and enduring personality difficulties has fallen into disrepute. It is now recognised that these ideas arose from, and perpetuated, the stigma that has burdened people with epilepsy since ancient times. Descriptions of epileptic personalities in the medical literature of the nineteenth century were often pejorative and demonstrably fostered social discrimination. To take one example, Devinsky and Najjar (1999) point out that eugenic laws in the USA barring people with epilepsy from marriage were influenced by the prevailing medical view that epilepsy was associated with 'mental and moral weakness'. It is disquieting to learn that such laws remained in force in a few States as recently as 1966. Fortunately, medical opinion and legislation have moved on. As previously noted in this chapter, it is now clear that the overwhelming majority of people with epilepsy suffer no mental disorder. Yet there is a risk that the controversy surrounding links between epilepsy and personality might lead us to overlook some genuine associations and potentially useful insights into the relationship between brain and behaviour.

The subject of personality and epilepsy has been reviewed by a number of authors (Trimble 1983; Benson 1991; Blumer 1999; Devinsky & Najjar 1999). The idea that TLE, rather than epilepsy in general, was specifically implicated in personality disturbance began with Gibbs (1951) who reported clinical observations in 275 patients with 'psychomotor' epilepsy. He found that psychiatric disorder, which he divided into either 'severe personality disorder' or 'psychosis (all types)', was three times more common in patients with an anterior temporal lobe focus compared with those who had foci elsewhere. Gibbs' influential conclusion was that 'the sylvian fissure is one of the chief boundaries between neurology and psychiatry'. In 1975, Waxman and Geschwind proposed a syndrome of interictal behavioural changes they believed to be common in TLE. Geschwind syndrome, as it came to be known, comprised alterations in sexual behaviour

(principally hyposexuality), religiosity and a tendency towards extensive, and in some cases compulsive, writing and drawing (hypergraphia). Waxman and Geschwind believed this behavioural syndrome was sufficiently distinct and common to be of diagnostic value. They also proposed the syndrome as a paradigm for linking human behaviour with a precise cerebral localisation. Bear and Fedio (1977) subsequently incorporated these traits with others gleaned from earlier descriptions in their 18-trait Bear and Fedio Index (BFI). In a small study involving 27 patients with presumed TLE, they found that the great majority of the chosen traits differentiated the epileptic patients from healthy controls and subjects with neuromuscular disorder. Particularly striking differences were seen with humourlessness, circumstantiality, dependence, sense of personal destiny and preoccupation with philosophical concerns. The profiles of traits tended to differ according to the hemisphere primarily involved. Patients with right temporal foci showed an excess of overt emotional traits (deepened emotionality, sadness, hypermoralism), whereas those with left temporal foci showed ruminative intellectual tendencies (religiosity, philosophical interests, humourlessness, sense of personal destiny).

However, further studies have thrown doubt on many of these associations. Bear and Fedio's initial study failed to include patients with other forms of epilepsy, nor did it control for the presence or absence of psychiatric disorder. Hermann and Riel (1981) compared patients with TLE and patients with primary generalised epilepsy, and found that only four of the traits differentiated them significantly (sense of personal destiny, philosophical interests, dependence and paranoia). Mungas (1982) found that no trait discriminated between patients with TLE and patients with psychiatric disorder; indeed when examined in a separate group of patients, a large proportion of the variance in the trait scores seemed attributable to the presence or absence of psychiatric illness. Master *et al.* (1984), in a thorough study, compared patients with TLE, other forms of epilepsy, psychiatric disorder and normal volunteers. The results again underlined the prominent effect of psychiatric disturbance. TLE made no discernible contribution of its own, and no differences in trait scores were observed between patients with right or left temporal lobe foci. In a critical review of the area, Devinsky & Najjar (1999) drew a number of conclusions. First, patients with epilepsy obtain higher scores on the BFI than healthy controls. Second, BFI scores do not discriminate between individuals with epilepsy and patients with psychiatric disorder who do not have epilepsy: the BFI is to some extent simply a marker of general psychopathology. Third, studies that have compared the BFI in patients with different forms of epilepsy have been inconclusive. In summary, while these studies contribute to the evidence that patients with epilepsy have higher rates of psychiatric morbidity than the general population, they have not identified behavioural traits that are

specific to epilepsy. The BFI does not define an epileptic behavioural syndrome.

Yet the possibility remains that a subgroup of patients with TLE may display significant clustering of some components of the syndrome, perhaps especially in the presence of psychiatric disorder. The search for clearly definable traits, and their detailed associations, still has much to commend it. Considerable interest still attaches to phenomena such as hypergraphia. Sachdev and Waxman (1981) wrote to patients inviting them to describe their current state of health. Patients with TLE responded more frequently and extensively (mean 1301 words) compared with other epileptic patients (mean 106 words). Hermann *et al.* (1983) replicated the higher response rate in patients with TLE. Further associations have been described between hypergraphia in TLE and measures of general psychopathology (Hermann *et al.* 1988; Okamura *et al.* 1993), right-sided epileptic foci (Roberts *et al.* 1982) and brain damage (Okamura *et al.* 1993). Other phenomena may prove better accounted for by disorders well recognised outside the field of epilepsy. Viscosity, for example, refers to a tendency for prolonged social contacts, talking repetitively, circumstantially, pedantically, and not ending conversations after a socially appropriate interval. It is essentially an abnormality of language and social communication that might suggest a diagnosis of autistic spectrum disorder, especially if it were associated with other 'temporal lobe personality' features such as obsessionality.

The possibility that other epilepsy syndromes may be associated with specific personality features has received less attention. Janz's (1969) original description of JME included a variety of behavioural traits that he felt were characteristic. These included such features as irresponsibility, impulsivity, self-centredness, and emotional instability. This suggestion has not been systematically investigated and many of these characteristics might simply be attributable to adolescence. However, some indirect support comes from a study by Gelisse *et al.* (2001) who found 11 patients meeting DSM-IV criteria for borderline personality disorder among a consecutive series of 170 patients with JME. This finding is in marked contrast with those from studies of TLE that have not reported high rates of borderline personality disorder (see below). Borderline personality disorder is characterised by a number of traits reminiscent of Janz's description including impulsivity and emotional instability.

Juvenile absence epilepsy has traditionally been regarded as benign, in terms of both seizure outcome and psychiatric comorbidity. This view has recently been challenged in a thorough study by Wirrell *et al.* (1997). These authors compared psychosocial outcome in 65 patients with juvenile absence epilepsy and 76 patients with juvenile rheumatoid arthritis. The mean age at assessment was 23 years. Patients with juvenile absence epilepsy had significantly greater difficulties in terms of academic achievement, interpersonal relationships and behavioural problems. Outcome was least

favourable in those (33%) who had ongoing seizures. At present, whether these problems reflect higher rates of formal psychiatric diagnoses, including personality disorder, is not known.

The relationships between personality and localisation-related epilepsies other than TLE have not been investigated. This seems particularly surprising in the case of FLE, which might be expected to be associated with distinct behavioural characteristics. Early descriptions of the syndrome (Williamson *et al.* 1985) noted that the majority of patients had a psychiatric history but the nature of this comorbidity has yet to be fully described.

The development of modern classification systems for mental disorders has provided a new framework for investigating personality in epilepsy. Two studies using DSM-III-R criteria have estimated the prevalence of personality disorder among epilepsy patients undergoing presurgical evaluation to be 18% and 22% (Manchanda *et al.* 1996, Lopez-Rodriguez *et al.* 1999). Neither study had a control group. However, these figures represent approximately twice the expected prevalence in the general population. Patients with dependent and avoidant personality disorder were particularly over-represented in both studies. In a detailed investigation of neurological variables, Lopez-Rodriguez *et al.* found a highly significant relationship between personality disorder and epileptic aura. No patient who did not experience an aura had a personality disorder. There were no associations with type of epilepsy or laterality, and no relationship with age at onset, duration of epilepsy or seizure frequency. These authors discuss possible explanations for the excess of dependent/avoidant personality disorders. Their findings may reflect an understandable reaction by patients to the psychosocial consequences of their illness, including the perceived stigma, and the loss of a sense of self-control that might be a consequence of unpredictable and disabling seizures. They also suggest biological mechanisms, citing evidence from animal studies linking mesolimbic lesions with social cohesiveness, fearfulness and avoidance. The association between personality disorder and epileptic aura is an intriguing one and mirrors earlier reports of an association between aura and both depression and psychosis. Again, the link could have a psychological basis. Avoidant or dependent traits might develop as a reaction to frightening and unwanted experiences. Or there may be some (unknown) difference in the biological substrate of seizures with and without aura that influences behaviour and personality. Such studies, using established diagnostic criteria and validated diagnostic interviews, offer a promising way forward in our attempt to understand the relationship between epilepsy, behaviour and personality.

Epilepsy and sexual dysfunction

Reduced libido and disorders of sexual function are over-represented in people with epilepsy (Lambert 2001). Men

with epilepsy report less sexual interest than healthy controls and a history of erectile dysfunction is found in up to 57% (Toone *et al.* 1989; Montouris & Morris 2005). In women, hyposexuality has been a less consistent finding, but abnormalities of arousal and orgasmic dysfunction are relatively common (Harden 2005). In both men and women, psychosocial factors are undoubtedly important causes in many cases. Thus, sexual difficulties may be one consequence of the more general impact intractable epilepsy may have on confidence, self-esteem, social activity and interpersonal relationships. Occasionally, sexual difficulties may relate specifically to a fear of having a seizure during sex. However, some sexual problems in epilepsy undoubtedly have an organic basis. In particular, abnormalities of sex hormone metabolism, secondary to antiepileptic drug treatment, are an important and potentially reversible cause. Direct physiological links with TLE have also been suggested.

Antiepileptic drugs that induce hepatic enzymes (most notably phenobarbital, phenytoin and carbamazepine) increase circulating sex hormone-binding globulin. Consequently, the level of physiologically active (unbound and loosely bound) testosterone is reduced. Several studies have demonstrated that sexual dysfunction in men with epilepsy is associated with reduced levels of biologically active testosterone (Toone *et al.* 1983; Macphree *et al.* 1988; Isojarvi *et al.* 1995). In a more recent study of men with localisation-related epilepsy, those taking lamotrigine (which has little effect on hepatic enzymes) were found to have similar sexual functioning to normal controls and had significantly higher levels of free testosterone compared with men taking either carbamazepine or phenytoin who in turn had higher rates of sexual dysfunction (Herzog *et al.* 2005). A similar association between low free testosterone levels and sexual dysfunction has recently been reported in women with epilepsy (Herzog *et al.* 2003).

Higher rates of sexual disorder have been reported in patients with localisation-related epilepsy compared with generalised epilepsy (Gastaut & Collomb, 1954; Shukla *et al.* 1979; Toone *et al.* 1989). A specific association with right-sided temporal lobe foci has also been reported (Herzog *et al.* 1990; Daniele *et al.* 1997). Physiological disturbance of limbic brain regions implicated in sexual function, such as the amygdala and cingulate cortex, is a plausible mechanism for these findings but other differences between epilepsy syndromes, including the likelihood of remission and the type of drugs prescribed, may also be important.

Crime and epilepsy

Early writers such as Lombroso (1911) came to the unfortunate view that epilepsy and criminality were intimately related. Most criminals were even thought to have an 'epileptoid' constitution: 'If fully developed epileptic fits are often lacking in the born criminal, this is because they remain latent, and only show themselves later under the influence of

the causes assigned (anger, alcoholism), which bring them to the surface.' Violent crimes were believed to be particularly characteristic. Maudsley (1873, 1906) thought that epilepsy should always be considered in aggressive crimes, and felt that crimes committed suddenly and in a 'blind fury' were often due to some form of epileptic process.

These views were decisively altered when careful surveys were carried out. Alstrom (1950) found no excess of criminal records compared with the population generally in 897 patients with epilepsy attending a Swedish clinic, provided they were not mentally affected. Those with psychiatric complications did show a significant excess, though the figure was not strikingly high (12% vs 5%). Major aggression was not observed in the sample, and the acts of violence that had occurred were usually trivial and closely connected with abuse of alcohol. Juul-Jensen's (1964) large Danish survey of 1020 adults with epilepsy substantially confirmed these findings. Both surveys, however, were largely confined to patients attending hospitals and clinics. Gudmundsson's (1966) attempt to survey all people with epilepsy resident in Iceland (987 individuals) produced rather different results: the men with epilepsy had been convicted three times as often as the male population generally.

Gunn approached the problem by an extensive survey of the prevalence of epilepsy among the prison and borstal populations of England and Wales (Gunn 1969; Gunn & Fenton 1971). At a conservative estimate, seven to eight prisoners per 1000 were found to be suffering from epilepsy, which is considerably higher than the prevalence of epilepsy in the general population. Young prisoners in particular were more likely to be suffering from epilepsy than persons of a similar age in the community. It seems therefore that people with epilepsy do have a higher probability of being committed to prison than other members of the population.

A representative sample of prisoners with epilepsy was then examined to see whether the types of crime committed differed from those of matched controls (Gunn & Bonn 1971). The great majority had been convicted for non-violent larceny, as with prisoners generally. There was no suggestion that epilepsy was associated with any particular form of offence, and no support for the view that crimes of violence were over-represented. Whitman *et al.* (1984) confirmed these findings in a survey of men entering the Illinois prison system; the prevalence of epilepsy was again raised, but there was no excess of more serious or violent crimes.

Nevertheless, the question arises whether violence may occur as a direct consequence of seizures or postictal automatisms. Most now agree that although this may happen it is very rare indeed. For example, Gunn and Fenton (1971), in a survey of 158 prisoners with epilepsy, found five who had seizures just after committing a crime, four who had seizures just before committing a crime, and four others in whom a possible association with automatism could be considered. In only one case was there evidence that murder had been

committed during the course of an epileptic seizure or its immediate sequelae (Gunn 1978). Moreover, among 32 patients with epilepsy committed to Broadmoor Special Hospital, Gunn and Fenton (1971) found only two who had probably committed their crimes during a postictal state. Treiman (1986) reviewed 75 legal cases from the USA in which epilepsy had been used as a defence against charges of violent crime. The defence was accepted by the courts in only one case, a man who it was subsequently concluded had almost certainly never had epilepsy.

However, aggressive behaviour during ictal automatisms is occasionally reported. The patient may continue with an act in progress at the time and do harm by virtue of a confused state of mind. A patient mentioned by MacDonald (1969) was filling a kettle with a view to placing it on the fire when her seizure commenced, and she placed her baby on the fire instead. Such situations are, however, exceedingly rare, and acts of violence have emerged as distinctly unusual in reviews of patients subject to automatisms (Knox 1968; Treiman 1986). Most ictal or postictal aggressive behaviour is reactive or 'resistive', arising in the context of agitation and delirium as a response to confinement, restraint or some other interference by bystanders. Delgado-Escueta *et al.* (1981) reviewed video recordings of 33 seizures in 19 patients, selected from over 5000 as showing possible aggressive behaviour. Only seven were rated as showing substantial aggression, usually in the form of struggling when restrained or kicking out in fear, but three showed elements of physical attack with spitting, shouting or scratching and three attempted to destroy property. Gerard *et al.* (1998) have described six cases of postictal aggression. Postictal psychosis clearly accounted for aggression in two patients. In three cases, a period of recovery from postictal delirium lasting several hours preceded prolonged episodes of aggressive behaviour lasting up to 3 days. Although psychotic symptoms were not documented in these cases, the occurrence of a lucid interval (see Postictal disorders) suggests some overlap with postictal psychosis. In the final case, however, aggressive behaviour arose after a brief period of postictal sleep. In this patient aggression had some resistive qualities but was also directed, relatively stereotyped, recurred frequently and was prolonged.

A 32-year-old man developed complex partial seizures aged 8. Seizures were initially well controlled with phenobarbital. In his teenage years he began using marijuana and cocaine. At this time his family noticed a change in his postictal behaviour. Following a seizure, complex partial with or without secondary generalisation, he would routinely sleep for 10–15 minutes. He would then awaken and often wander around aimlessly. If approached, even if only verbally, he would direct obscenities towards the person, and

would often use physical force to push the person away. If the patient's mother was in the vicinity, he would actively seek her out, and display physical and verbal aggressive behaviour towards her alone. On one such occasion he held a knife to her throat. This aggressive behaviour typically lasted from 20 minutes to 1 hour, with gradual resolution to his baseline mild-mannered temperament. Interictally, he had no recollection of these events and showed considerable remorse afterwards. His postictal disturbance continued for 6 years despite not using alcohol or illicit substances. Anterior left temporal lobectomy was performed. Pathology showed mesial temporal sclerosis. Two seizures in the first 6 months following lobectomy were also accompanied by postictal aggression towards his mother.

Violence arising as a direct consequence of seizures is thus very rare. It usually represents a confused defensive reaction to attempts by others to restrain or assist the patient, actions that the patient appears to misconstrue as threatening. Such behaviour is brief, lasting only for the duration of postictal delirium. More prolonged aggressive episodes appearing after a period of recovery from seizures are sometimes associated with postictal psychosis. As detailed above, careful studies of people with epilepsy who have committed crimes have identified very few cases in which criminal acts have occurred during a seizure. The majority of criminal behaviour in people with epilepsy is therefore interictal and has little to do with the occurrence of seizures *per se* (Marsh & Krauss 2000). Furthermore, such criminal behaviour is no more likely to be violent than crime committed by people without epilepsy. Many factors that coexist with epilepsy are likely to underlie the association. Sociodemographic factors associated with offending behaviour in the general population, including various indices of social deprivation, are over-represented in people with epilepsy and undoubtedly underlie much of the association between epilepsy and criminal behaviour (Treiman 1986). Among medical variables, by far the most important factors are the presence of underlying brain damage and cognitive impairment (Stevens & Hermann 1981). Interictal psychopathology, particularly psychosis, may also be significant (Mendez *et al.* 1993b).

It can be important in medicolegal work to have guidelines for assessing the probability that a crime may have been committed during an episode of ictal or postictal confusion. In legal terms, an automatism occurs if an act is committed but was neither intended nor the result of recklessness (i.e. there is *actus rea* but no *mens rea*). In the UK legal automatisms are categorised as 'sane' if they arise from extrinsic causes (e.g. an acute head injury) or 'insane' if they arise through intrinsic causes (e.g. epilepsy). Prior to the 1991 Criminal Procedure Act, the defence of insane automatism attracted mandatory detention under Sections 37 and 41 of the Mental

Health Act, a situation that was obviously inappropriate for criminal acts committed in the context of epileptic or sleep automatisms. The Act gave the courts freedom to choose from a range of outcomes, including hospital treatment, guardianship, supervision and treatment, or absolute discharge (Brown & Bird 2001). A number of authorities have discussed criteria that may be applied in mounting a defence of automatism (Walker 1961; Knox 1968; Fenton 1972; Treiman 1999).

First of all, the patient should have a past history of unequivocal epileptic seizures. There need not necessarily be a previous history of aggression during automatism as such, though clearly when this is elicited it will strengthen the confidence with which the present example is so diagnosed. The diagnosis must always be made on clinical grounds, for epilepsy can occur in the presence of a normal EEG and, conversely, abnormal records may be obtained in patients who have never had a clinical attack. Nevertheless, an EEG compatible with the type of clinical disorder presumed to be present will constitute important additional evidence. Clearly video-EEG documentation of automatisms and associated aggressive behaviour will greatly strengthen the case.

With regard to the circumstances of the crime itself, this will always have been sudden, obvious motives will be lacking and there should be no evidence of planning or premeditation. The crime will appear to be senseless, there will typically have been little or no attempt at concealment and often no attempt at escape. The abnormal behaviour will usually have been of short duration, lasting minutes rather than hours, and will never have been entirely appropriate to the circumstances. Witnesses may have noted evidence of impairment of awareness, for example inappropriate actions or gestures, stereotyped movements, unresponsiveness or irrelevant replies to questions, aimless wandering around, or a dazed and vacant expression. However, these features may not be readily apparent to the untrained eye. Amnesia for the crime is the rule, but there should be no continuing anterograde amnesia for events following the resumption of conscious awareness. The more that these criteria are not fulfilled, the more will an epileptic basis for the act be regarded with suspicion.

Cognitive function in epilepsy

Although most people with epilepsy function within the normal range of cognitive ability, comparisons with appropriate control groups consistently demonstrate deficits (Motamedi & Meador 2003; Elger *et al.* 2004). There is now good evidence that such cognitive deficits are present at the time epilepsy is first diagnosed and may even precede the onset of seizures. This is hardly surprising when seizures are symptomatic of gross underlying brain disease. However, evidence of early cognitive deficits has also emerged from studies of patients with idiopathic and cryptogenic epilepsy. For example, Hermann *et al.* (2006) compared 53 children with epilepsy with 50 healthy controls (age- and gender-matched first cousins of the patients). Patients were included only if neurological examination and clinical MRI were normal and the patient group included almost equal numbers of subjects with generalised and localisation-related

epilepsy. Neuropsychological testing, conducted on average 10 months after the onset of seizures, demonstrated a broad range of mild cognitive impairments that were present in both epilepsy syndromes. Of the children with epilepsy, 26% had a history of academic problems (compared with 4% of controls) and in the majority of cases these were identified by educational services before the first recognised seizure. Strong correlations between neuropsychological performance and morphometric brain measurements (white-matter volumes measured with MRI) were seen in the healthy controls but not in the patients in this study. This loss of normal structure–function relationships might have a number of explanations, including pathological disturbance of white matter connections or an overriding influence of other epilepsy-related variables on cognition.

Cognitive profiles and epilepsy syndrome

The pattern of cognitive impairment in chronic epilepsy varies according to the underlying epilepsy syndrome. TLE is the most common localisation-related syndrome and also the most common type of epilepsy treated surgically. The neuropsychological profile of TLE is therefore well characterised. While patients with TLE may show significant impairments across all cognitive domains, selective deficits in episodic memory are characteristic (Hermann *et al.* 1997). Left-sided TLE is associated with deficits in verbal episodic memory. Non-verbal memory deficits are associated with right-sided TLE, although findings are less consistent (Gleissner *et al.* 1998). The lateralisation of language dominance has a strong influence on these material-specific memory deficits. Thus, Kim *et al.* (2003) found clear evidence of the expected pattern of lateralised deficits in patients with left hemisphere language dominance. However, in patients with right or mixed hemisphere language dominance these associations were not seen. Hemispheric language dominance was determined by testing after intracarotid amobarbital in this study. The authors comment that failure to specify hemispheric language dominance, or using less stringent definitions of language dominance, might account for some of the many inconsistent findings in the literature. Memory deficits in TLE are most conspicuous in patients with evidence of hippocampal atrophy on MRI (Alessio *et al.* 2004). More generalised cognitive deficits in TLE have recently been correlated with measures of extratemporal anatomical abnormalities (Hermann *et al.* 2003).

There have been fewer investigations of cognitive function in FLE and most studies have included a large proportion of patients with acquired frontal lobe lesions. Whether frontal lobe seizures have a specific effect on cognition, independent of underlying pathology, has therefore not been established. Overall, there is an impression that FLE may be associated with relatively little in the way of cognitive deficits, especially when there is no demonstrable lesion. Where deficits are found, the profile is what might be expected in

association with frontal lobe damage, with impairments in psychomotor speed, attention, working memory, response-inhibition and planning, set against a background of variable general impairment (Helmstaedter *et al.* 1996; Upton & Thompson 1996; Exner *et al.* 2002).

The conventional view that the idiopathic epilepsy syndromes are benign in terms of cognitive outcome has recently been challenged (Wirrell *et al.* 1997; Hommet *et al.* 2006). Studies of children and adults with idiopathic generalised epilepsy have demonstrated mild cognitive deficits that are present early in the natural history of the disorder (Pulliainen *et al.* 2000; Hermann *et al.* 2006). Whether abnormalities persist after seizures have resolved in the benign idiopathic syndromes has not been established. Overall, subtle general deficits have been described, but selective dysexecutive problems in areas such as concept formation, reasoning, planning, mental flexibility and working memory implicating frontal lobe abnormality have been demonstrated in patients with JME (Swartz *et al.* 1996; Devinsky *et al.* 1997). In view of the overlap between idiopathic generalised epilepsy syndromes it seems possible that similar deficits occur in other syndromes but this has not been systematically explored. Among idiopathic localisation-related syndromes, cognitive deficits have been demonstrated in benign childhood epilepsy with centrottemporal spikes (Weglage *et al.* 1997; Metz-Lutz *et al.* 1999; Northcott *et al.* 2006) and in idiopathic occipital lobe epilepsy (Gulgonen *et al.* 2000). The deficits in childhood epilepsy with centrottemporal spikes may correlate with the frequency of interictal EEG abnormalities. These disorders have an excellent outcome in terms of seizure resolution but there is some preliminary evidence that subtle cognitive problems may persist (Northcott *et al.* 2006).

Progressive cognitive impairment

An important question is whether epilepsy may cause progressive cognitive impairment. Just over a century ago, Berkley (1901) wrote

The most numerous class of epileptics show, after the lapse of years, a slowly progressive dimming of the active perceptions of the mind, a loss of memory, a blunting of the affections, a permanent mental obtuseness which increases and grows, until, if the patient lives long enough, there is a more or less absolute annihilation of all the faculties.

This statement, which today seems so wide of the truth, perhaps serves as a reminder of just how profound the impact of modern epilepsy treatment has been. Yet a small proportion of people with epilepsy do appear to suffer some progressive cognitive impairment and many studies have attempted to define the extent of this. Cross-sectional studies are unable to distinguish clearly between the static effects of underlying brain abnormality and deficits acquired over time. Longitudinal studies are required to properly investi-

gate whether intellectual impairments are progressive and to elucidate their causes. Over 20 such studies have now been published (reviewed by Dodrill 2004; Vingerhoets 2006). Early studies are difficult to interpret because epilepsy syndromes were not well defined and seizure frequency was often poorly documented. Among more recent investigations, surprisingly few have used appropriate comparison groups to control for test–retest effects on neuropsychological assessments. In reviewing the evidence, it is logical to consider studies of children and adults separately. The former seek to investigate the impact of epilepsy on intellectual development while studies of adults are concerned with the question of intellectual deterioration.

In a study of 83 preschool children with relatively infrequent seizures, Ellenberg *et al.* (1986) found no decline in IQ measures over a 3-year period. However, two studies (Bourgeois *et al.* 1983; Aldenkamp *et al.* 1990) of slightly older children (of primary school age) with more active epilepsy found that 11 and 24% respectively showed a decline in IQ measures of 9 points or more over an interval of approximately 4 years. Bourgeois and colleagues found the impaired group was characterised by more frequent seizures, toxic drug levels and younger age at onset of epilepsy. In a small controlled study, Neyens *et al.* (1999) investigated 11 children with epilepsy aged 7–15 years and 39 controls on three occasions over 18 months. The patient group showed lower IQ levels at baseline and less improvement in test performance over time. Most recently, Ostrom *et al.* (2005) compared 42 children with newly diagnosed idiopathic or cryptogenic epilepsy and 30 healthy gender-matched classmates over a 3.5-year interval on a comprehensive neuropsychological battery and behavioural checklist. Most of the children became seizure-free within the first 2 years of the study. A minority of the patient group (19%) had persistent cognitive difficulties. This group was no different in terms of epilepsy variables, including whether they became seizure-free, from those with better cognitive functioning, but psychosocial measures, such as poor parental adjustment to their child's diagnosis, adverse family situations and the prior existence of behavioural problems, were over-represented.

In adults, longitudinal studies have involved patients with localisation-related epilepsy, mainly TLE. A consistent finding has been that measures of global IQ remain relatively stable. However, there is growing evidence of progressive memory impairment. Helmstaedter *et al.* (2003) found a significant deterioration in tests of verbal and visual memory in 50% of 102 patients with intractable TLE over an average time interval just short of 5 years. Andersson-Rosswall *et al.* (2004) compared IQ and memory tests in 36 patients with partial seizures and 36 controls over 3–4 years. IQ and memory function were lower in the patients at baseline. IQ scores did not deteriorate, although they failed to show the improvement (presumably due to practice effects) seen in controls. However, 25% of patients demonstrated a deteriora-

tion in verbal memory that was not seen in the controls. In another controlled study, Dodrill (2002) was unable to demonstrate a deterioration in the epilepsy group but did show less improvement in scores in patients compared with controls over an interval of 10 years. The pathological substrate for these memory deficits may be progressive medial temporal lobe damage secondary to ongoing seizure activity. Progressive hippocampal atrophy has been reported by some recent longitudinal MRI studies of TLE (Briellmann *et al.* 2005), although there have also been negative findings (Holtkamp *et al.* 2004).

In summary, longitudinal studies suggest that a minority of children with epilepsy, perhaps 10–20%, will suffer impaired intellectual development manifest as persistent or progressive cognitive deficit. Those with poorly controlled epilepsy appear most at risk but psychosocial variables may be equally important predictors of cognitive outcome. In adults, progressive decline in memory has been described in up to 50% of patients with poorly controlled TLE and this may be related to progressive hippocampal atrophy secondary to intractable seizures.

Causes of intellectual deterioration in poorly controlled epilepsy

Cognitive deficits in epilepsy, whether static or progressive, may have a number of causes. They may reflect the underlying cerebral disorder of which epilepsy is also a symptom. Alternatively, cognitive decline may be due to a number of factors directly related to epilepsy. Potential causes in this category include possible cumulative effects of neuronal damage incurred through repeated seizures, brain injury secondary to trauma or status epilepticus, the effects of drug treatment and, finally, the psychosocial impact of the disorder.

The majority of studies have found a relationship between cognitive impairment and measures of seizure frequency. However, there have been many negative findings, leading Dodrill (2004) to conclude that overall the evidence favours a relatively weak relationship between seizures and cognitive decline. Secondary generalised tonic–clonic seizures may be a more important factor than the frequency of partial seizures. Evidence for an association between duration of epilepsy and cognitive deterioration is similarly inconsistent and may only be demonstrable after a relatively long history (over 30 years) of intractable seizures (Jokeit & Ebner 1999). Prolonged or recurrent status epilepticus may result in permanent brain injury but there is little evidence concerning the impact of a history of status, or of seizure-related head injury, on cognitive outcome in epilepsy (Dodrill 2002).

Related to the issue of an association between seizures and cognitive decline is the observation that subclinical epileptiform discharges (demonstrated on EEG but not associated with overt clinical seizures) may be accompanied by transitory cognitive impairment (TCI) (Binnie 2003; Aldenkamp &

Arends 2004). The paradox of defining this condition by demonstrating a clinical effect (cognitive dysfunction) during an event which is designated subclinical has led to some debate about semantics, and clearly TCI could be regarded as a form of simple partial seizure whose sole manifestation is cognitive. The cognitive impairments are best demonstrated with tasks that involve high information-processing demands. The epileptiform discharges in question are typically around 3 seconds in duration, longer discharges being more likely to be accompanied by an overt clinical seizure. TCI is a relatively rare phenomenon and is demonstrable in less than 2% of patients with epilepsy. Cases in which TCI is a primary cause of ongoing cognitive or functional disability are likely to be much rarer still. A few case reports suggest that treatment aimed at reducing subclinical discharges may improve function in patients with carefully documented TCI. However, further research is required to assess the functional impact of TCI, including whether there are cumulative effects on cognitive function, and to establish management guidelines.

Antiepileptic drugs are an important cause of cognitive problems in people with epilepsy (see reviews by Vermeulen & Aldenkamp 1995; Kwan & Brodie 2001; Meador 2002). Deficits in psychomotor speed and attention are characteristic, with secondary effects on other cognitive domains. Adverse cognitive effects are especially likely in patients taking two or more antiepileptic drugs. This may be due to pharmacokinetic interactions, or to additive pharmacodynamic effects. The cognitive effects of antiepileptic drugs are typically dose related and may appear in association with other symptoms of neurotoxicity. However, idiosyncratic responses are sometimes encountered in which individual patients are intolerant of even low doses of specific drugs. Cognitive side effects are especially likely in patients with learning disability and in the elderly. Patients commonly develop tolerance to the adverse cognitive effects of antiepileptic drugs and an important strategy in clinical practice is to slow the rate at which drug dosage is increased. This is especially important when prescribing an antiepileptic drug as add-on treatment. Many studies have attempted to compare the cognitive profiles of different antiepileptic drugs. The field is beset with methodological difficulties but some conclusions have emerged. Phenobarbital is generally agreed to be associated with the worst cognitive effects. Phenytoin, carbamazepine, valproate and clonazepam probably have similar profiles. Among benzodiazepines, clobazam may be preferable to clonazepam. Of the newer antiepileptic drugs, lamotrigine and gabapentin have a favourable cognitive profile compared with older drugs. Topiramate may cause severe cognitive effects and has been associated with specific deficits in word-finding and verbal fluency. However, cognitive problems with topiramate are less likely, and may even be avoided, when the dose is titrated slowly. There are insufficient data on other more recently introduced

antiepileptic drugs, although there is a general impression that they have a relatively favourable cognitive profile compared with older drugs.

Finally, psychosocial factors have an important moderating influence on the relationship between cognitive ability in children with epilepsy and educational achievement. Persistent cognitive difficulties in children with epilepsy are associated with measures of poor parental adjustment and adverse family circumstances (Fastenau *et al.* 2004; Ostrom *et al.* 2005). The relationship between these factors is undoubtedly complex; cause and effect are difficult to determine. However, there is some evidence that emotionally supportive and well-organised families may ameliorate the negative impact of neuropsychological impairment on educational achievement (Fastenau *et al.* 2004). Psychosocial interventions for families struggling to cope with their child's epilepsy may prove to be important in determining long-term outcome.

Dissociative seizures
